ORIGINAL LECTURES.

ON LOCAL ANÆSTHETICS.[1]

A Clinical Lecture, delivered in Cochin Hospital.

BY PROFESSOR DUJARDIN-BEAUMETZ,

OF PARIS, FRANCE.

GENTLEMEN: In the present lecture I propose to consider the new anæsthetics, and omitting altogether surgical anæsthesia in its various bearings and uses, which would require a whole course of lectures, I shall take up only one of the minor aspects of the question, and discuss the subject of local anæsthesia, which presents no little interest at the present day.

For a long time clinicians have sought to diminish or abolish the sensibility of the skin in regions where the minor surgical operations, such as simple incisions of the skin and cellular tissue, were to be performed. This was considered the more desirable, inasmuch as grave accidents sometimes attended the first attempts at general anæsthesia. One of the means most employed was cold.

It was, in fact, known that when cold strikes the exposed parts of the body it produces numbness and insensibility, and practitioners had recourse not only to local applications of ice, but also to refrigerant mixtures. Hence it was that James Arnott, of Brighton, many years ago, advised the combination of ice and common salt, and Adolph Richard, that of sal-ammoniac, salt, and ice.

One may also obtain this local anæsthesia by the rapid evaporation of volatile substances, such as ether, and Simpson was one of the first to counsel this mode of refrigeration. I remember to have seen, thirty years ago, at the commencement of my medical studies, a very ingenious apparatus, made according to the plan of Prof. Richet, which consisted in a pair of bellows over which was placed a reservoir of ether; as fast as the stream of ether was projected on the exposed surface of the skin, it was volatilized by the blast from the bellows. This apparatus, which was rather cumbersome, was advantageously replaced by Richardson's spray producer, of which we make use at the present day.

The atomization of ether as a process of local anæsthesia possesses great advantages over the local application of ice or refrigerant mixtures; nevertheless, these sprays are not free from the other inconveniences of refrigeration. Cold does, in fact, abolish sensibility, but during the application of the cold the pain is quite keen and when the anæsthesia has disappeared, the pain returns more pungent than before, so that if one suffers but little during the operation, the after-effect is quite painful; moreover, the reaction is sometimes followed by profuse hemorrhage. These are disadvantages which limit the usefulness of local anæsthesia by cold.

Other liquid substances have been substituted for ether, such as rhigolene, by Bigelow, of Boston, and Delcomenete, of Nancy, a few years ago, advised carbon disulphide as a means of local anæsthesia. I have myself been much interested in this subject of the local uses of bisulphide of carbon. This chemical, by reason of its extreme volatility, produces refrigeration of the tissues, but this refrigeration is rapidly followed by such intense rubefaction, that carbon disulphide ought rather to be considered a rubefacient of the first order, superior in many respects to mustard sinapisms, than as a local anæsthetic. It has also been proposed to employ certain gases for the production of local anæsthesia, and it is for this purpose that carbonic acid was recommended as early as 1772 by Percival. In 1856 Simpson again took up this means of local anæsthesia, improving the apparatus for its production, and it was then quite a common thing to see local douches of carbonic acid used in the hospitals of Paris, though rather for analgesic than for anæsthetic purposes; they were used chiefly to relieve the pains caused by cancer of the uterus. We have even seen this gas used in the treatment of neuralgias at the thermal stations, where are found waters highly charged with carbonic acid, as at St. Nectaire. Finally, in 1883, my friend, Dr. Campardon, following the ancient practice of Percival and Simpson, applied carbonic acid to the treatment of whooping-cough.

Thanks to the acknowledged anæsthetic properties of carbonic acid, it abolishes the exaggerated sensibility of the glottis, and thereby lessens the fits of coughing in pertussoid patients. The means employed by Campardon is very simple: it consists in utilizing the well-known soda water siphon bottles—the bottles which are in use for this purpose are destitute of tubes dipping into the liquid, and only the liberated gas issues from the mouth of the bottle. A rubber tube adapted to the siphon, and which the patient takes between his lips, conveys the gas into his mouth; the child makes a few inspirations, and Dr. Campardon affirms that by this means he has seen the paroxysms rapidly diminished. But I come now to a mode of local anæsthesia of much more recent date, and which is destined to render us great service; I refer to coca and cocaine.

From time immemorial, the Peruvians have made use of the leaves of a shrub belonging to a family of Erythroxylaceæ, the *Erythroxylon coca*. In their estimation, this leaf has multiple remedial properties, and, according to the statement of Dr. Beugnier-Corbeau, "the sacred plant of the Incas was a promise of life to the moribund who could drink its sap; an uncomparable viaticum to the traveller whose hunger it appeased; a cordial to raise the forces and revive the senses benumbed by the cold of the rugged winter; a source of sweet forgetfulness to the man harassed by chagrin;

[1] Translated, from advance sheets, by E. P. Hurd, M.D., of Newburyport, Mass.

and a joy-producer to him who would taste the pleasures of love."

When, twenty years ago, or a little more, it was proposed to introduce coca into therapeutics, it was chiefly its tonic and excitant properties which were vaunted; and you will find in the thesis of Damarle, and in the writings of Reis, indications relative only to these tonic properties.[1] However, in 1860, Niemann had discovered in the leaves of coca a crystalline alkaloid having for its formula $C_{17}H_{21}NO_4$, to which he gave the name of *cocaine;* and, two years afterward, Walker and Lossen found another active principle, of syrupy consistence, having a very marked ammoniacal odor, to which they gave the name *hygrine*.

These chemical discoveries added nothing to our knowledge of coca till Koller made known, on the 16th of October, 1884, to the Medical Society of Vienna, the marvellous anæsthetic action of cocaine on the mucous membrane of the eye. You remember how great was the astonishment, and what incredulity was manifested; but soon the facts which Koller had announced were confirmed all over Europe. Abadie and Darier, Trousseau, Panas, and all the ophthalmologists in France, showed the great advantages which might be obtained in ocular therapeutics from the discovery of Koller, and the anæsthetic properties of cocaine were henceforth everywhere recognized. By what train of ideas was Koller led to make this grand discovery, which constitutes an epoch in the therapeutic history of this century? And how is it that coca, from being the tonic and waste-restraining medicament which it once was, has been transformed into a local anæsthetic? The history is so strange that you will allow me here briefly to relate the points of interest.

Morino y Maiz,[2] in his thesis of 1868, on cocaine (which, by the way, was the first that was ever written on this alkaloid), made mention of the following fact: "In large doses, cocaine produces in animals diminution, then annihilation, of sensibility, without motility being completely abolished; in all cases the pupil remains dilated."

In 1870, Gazeaux gave expression to certain doubts respecting the tonic and waste-restraining properties of coca, and thought that this medicament might act by allaying the sense of hunger and thirst through its anæsthetic effect on the lingual and gastric mucous membranes.

In fact, physicians who were engaged in treating affections of the larynx had noticed this special anæsthetic action of coca; and Fauvel, since 1869, was in the habit of using coca in laryngeal diseases.

In 1877, Saglia insisted anew on the advantages to be derived from the sacred plant of Peru in painful affections of the pharynx, and this anæsthetic action was so well shown that, in 1881, Du Cazal,[3] at the Medical Society of the Hospitals, thus expressed himself *a propos* of a case of tuberculous ulceration of the larynx presented by our colleague, Millard: "The tincture of coca is an excellent medicament with which to obtain anæsthesia of the pharynx, and to produce such anæsthesia it is only necessary to paint the mucous membrane with the tincture." Gougenheim,[1] in 1882, when writing of the local treatment of the laryngites, said: "The extract of coca, diluted in water, so as to form a very concentrated solution, produces a veritable sedation; I do not know the cause of this therapeutic action."

Moreover, the physiologists, on their part, did not remain inactive, and, in 1880, Von Anrep spoke of the pupillary dilatation, but had not observed the state of the mucous membranes. The following year, Coupard and Laborde noticed the anæsthetic action of cocaine. Unfortunately, their experiments remain incomplete, and the results have not been published.

Hence, then, gentlemen, as you see, what led Koller to his discovery was the knowledge of the local anæsthetizing properties of coca on the lingual and pharyngeal mucous membrane; he thought, and rightly, that all the mucous membranes must respond alike to the action of this medicament; and since then we have been able to add that even the skin submits to this anæsthetic action. It is unfortunate that the discovery of the local anæsthetic properties of cocaine was not followed up in France, where there had been so many investigations on this subject, and where, fifteen years before, the anæsthetic action of coca on the pharyngeal mucous membrane had been pointed out.

When you put in contact with a mucous surface a two per cent. solution of hydrochlorate of cocaine, you obtain, at the end of from five to ten minutes, loss of sensibility of the mucous membrane, and this effect lasts an hour or two. The anæsthetic action does not seem to exhaust itself by habit — that is to say, a second and third or any future application is as successful as the first. The same insensibility is produced when the cocaine is introduced under the skin, and in the experiments made under our direction by Dr. Paul Compain, and which you will find described in his inaugural thesis,[1] I studied thoroughly the anæsthetic action of hypodermic injections of this alkaloid.

You see before you a patient on whom we are about to experiment: we pinch up a fold of the skin of the forearm and inject twenty drops of a two per cent. cocaine solution. This injection, as you may see, does not cause any painful sensation. If in the course of five minutes, we explore the sensibility of the skin over the point of injection, this is what we shall observe: the sense of touch is obtunded, and the patient tells us that he feels as if the skin over that place were covered with a thick layer of wadding. The consciousness of painful impressions is abolished, and we may with impunity scratch or prick the part with a needle; the patient has over this region only the sensation of contact of a foreign body. This anæsthetic state of the skin is produced in only a very limited zone, which exactly corresponds with the portions of the derm which have been directly in contact with the solution of cocaine, and in our patient it represents a circular space of about an inch and a half in diameter. This complete anæsthesia of the skin lasts about twenty minutes, then disappears

little by little, and an hour after, there remains but a trace of the anæsthetic phenomena.

May these hypodermic injections be accompanied by general symptoms? Yes, in certain cases. In the first researches which were made in our laboratory by Drs. Bardet and Meyer, these experimenters affirmed that they had felt such general effects as, first, a marked dilatation of the pupil, coming on half an hour after the injection, then syncopal symptoms, so intense that one of them completely lost consciousness and fell on the floor—his face was pale and his pulse imperceptible; these symptoms returned whenever he assumed the erect posture.

Since then we have observed the same symptoms in a number of our patients. One of these was a woman on whom we wished to practise forcible dilatation of the anus; we injected around the margin of the orifice a syringeful of a two per cent. solution; there supervened syncope, nausea, and curious twitchings of the alæ nasi.

I was recently consultant in a case in which I had ordered subcutaneous injections of cocaine, to combat a vehement intercostal neuralgia. The attending physician wished to experiment on himself with the same injection, after having administered it to the patient. In both of them there were very pronounced symptoms. The physician experienced an attack of syncope, while the patient had very strange sensations; he felt, he said, extraordinarily light, and he seemed to himself to be lifted up into the air like a balloon.

In all these cases the injections were practised with a two per cent. solution, and the dose did not exceed from one to two cubic centimetres. I must add that, in all these instances, the patients were standing or sitting, which postures would be likely to favor syncopal attacks. Hence it is that, since I have taken the precaution to make the patient lie down whenever I have administered the cocaine injection, these phenomena have not occurred.

To what causes must we ascribe these effects? Probably to the cerebral anæmia produced by the action of cocaine upon the vasomotor nerves; in fact, besides the considerable part which the dorsal position plays in the appearance or non-appearance of the general effects of cocaine, it is noteworthy that these general symptoms are the more likely to supervene, the more anæmic the patient is, and that they are inconspicuous when the patient is strong and vigorous. Hence it is that Dr. Compain has never seen such accidents produced as the result of the numerous injections which he has made on himself. Moreover, when experiments are performed with cocaine on animals, and particularly on the monkey, such as Prof. Grasset and Dr. Henri Negre have made, there appear convulsive phenomena characterized by attacks of clonic spasm, and this happens when the dose is reached of six cubic centimetres of a two per cent. solution.

Moreover, cocaine has an evident action on the temperature, which it raises; it is, therefore, a hyperthermic agent. This action, however, is very variable, according to the kind of animal experimented on; for, while cocaine raises the temperature in the dog, it lowers it in the monkey. In fine, my pupil Dr. Rigolet has noted *de visu* the modifications effected in the capillary system by the action of cocaine. Several drops of a one per cent. solution determine in the frog, at first a dilatation, then a contraction of the capillaries; and Rigolet considers this alkaloid a powerful vaso-constrictor. These experiments give us a physiological explanation of the general symptoms which in man are determined by cocaine.

However, thus far these accidents of a toxic kind have never presented any gravity, and to determine such constitutional effects it is necessary to employ pretty large doses. Thus, Rigolet has been able to inject, without any harm, 40 centigrammes in the veins of a dog weighing 18 kilogrammes. Likewise, Bignon, of Lima, has observed that the Indians can absorb as much as 40 centigrammes of cocaine in chewing the leaves, without experiencing any toxic manifestations.

Ordinarily, to obtain anæsthetic effects, we make use of a two per cent. solution of chlorhydrate of cocaine. According to the researches which I have made, the increase of the anæsthesia is not proportioned to the increase of dose, so that we may adhere to this two per cent. solution with the certainty of experiencing the desired results.

In certain cases we may employ pomades of cocaine, and in the preparation of these it is not necessary to transform the cocaine into a hydrochlorate. Bignon, of Lima, has, in fact, shown us that the alkaloids of coca are soluble in unctuous substances of mineral origin, such as vaseline; the dose here is the same as in the case of the solutions; finally, one can have recourse to preparations made from the plant itself. Delpech, in particular, has made an extract of coca according to the method of the American Pharmacopœia—that is, by evaporating the alcohol, and which is said to render good service in affections of the pharynx.

Before undertaking the consideration of the action of coca and its therapeutic applications, I desire to say a few words about its cost.

When Koller's discovery was first made known, cocaine readily brought a very high price, and this was the first drawback to its general use. I have, in fact, known physicians, ignorant of this high cost, to prescribe gargles, lavements, and ointments, the price of which exceeded twenty dollars. To-day cocaine is sold at a much cheaper rate, and you can find in our drug stores cocaine of impure quality, though still pure enough for all anæsthetic purposes, save in ophthalmic surgery, the price of which varies from four to six francs a gramme.

THERAPEUTIC APPLICATIONS OF COCAINE.

Cocaine is, as we have seen, a local anæsthetic of the mucous membrane and the skin. To begin with the subject of the production of cutaneous anæsthesia, it is necessary, in order that the cocaine may act, that it be applied to an abraded surface, or introduced under the skin. I have never obtained the least effect from the prolonged contact of cocaine with the undenuded skin, whether the alkaloid were rubbed over the derm in the form of concentrated solutions, or in the form of ointment.

When the skin is deprived of its cuticle, and cocaine is applied, the latter has a very marked anæsthetic action, and you can derive advantage from this property in the treatment of *burns* where solutions or pomades of this alkaloid at once dissipate the atrocious pain which accompanies burns in the first and second degrees. You

will obtain the same analgesic effects in the case of cracked nipples, so common in nursing women, and Audhoui has reported interesting instances of this kind. In certain pruriginous affections of the skin, moreover, cocaine may be used to allay the tormenting itching.

Administered under the skin, two per cent. solutions of cocaine enable us to perform, without pain, a great number of minor operations. It is with the help of this local anæsthetic that I now practise pleurotomy, and that I secure for the patient exemption from the pain of the first stage of the operation. To attain this result, I inject at both extremities of the line which my bistoury has to traverse a syringeful of a two per cent. solution of hydrochlorate of cocaine.

You may in this way, without pain, open a superficial abscess, or extirpate a lupus; the pain of incising a felon is much mitigated; by the help of cocaine, tracheotomy is robbed of half its terrors; and, in short, you will derive advantage from the local use of this alkaloid in all instances where the incision of the skin is the chief element of pain. In all these cases the local anæsthesia by cocaine is far superior to that produced by cold. Remember that you should always operate with the patient in a recumbent posture, to avoid the vertigo which might ensue, and you should wait ten minutes, at least, after the subcutaneous injection before proceeding to the incision of the skin.

By the aid of cocaine I have operated for phimosis, but if you are not very careful you will have difficulty in approximating the skin and mucous membrane with your *serre-fines* by reason of the artificial œdema produced by the injection of the cocaine solution in the cellular tissue of the prepuce.

I come now to the applications of cocaine to the affections of mucous membranes. I will omit what pertains to the ocular mucosa, this being the special province of the ophthalmologist, and I will consider rapidly the benefits derivable from cocaine in affections of the mucous membranes, commencing with the digestive tube.

The buccal and pharyngeal mucous membranes are readily and rapidly anæsthetized by cocaine. In operations on the pharynx, epiglottis, and larynx, generally so painful, you may make applications of this alkaloid, and you have often seen in my service tuberculous patients who could scarcely swallow a mouthful, enabled henceforth to eat by reason of relief from suffering obtained by the repeated use of solutions of this charming local analgesic. You all doubtless remember the case of the late General Grant, and the comfort which he obtained the last few months of his life from cocaine.

In the cases of which I have just spoken, the throat is painted with a strong solution of cocaine a few minutes before a meal, and the local anæsthesia lasts about three-quarters of an hour, giving ample time for the repast.

By means of these local applications of cocaine such operations as staphylorrhaphy are facilitated, and laryngoscopic examinations are rendered comparatively easy. It is also a good plan, in order to avoid the pain of amygdalotomy, either to inject a little cocaine into the tonsil, or, as Lermoyez advises,[1] to paint the tonsil over several times with a two per cent. solution before resorting to the operation. Moreover, the painful period in the performance of lavage or "gavage" of the stomach due to the contractions which take place in the isthmus of the fauces, may be obviated by painting with cocaine, and I have been careful to resort to this means whenever patients have experienced difficulty in the introduction of the stomach-tube.

But the anæsthetic action, so local and superficial, of cocaine can be of no service in toothache or in the extraction of teeth; on this point all the best dental surgeons, such as Galeppe and Magitot, are agreed.

Certain diseases of the œsophagus, such as spasmodic stricture, are tributary to the action of cocaine, which may be applied by means of the sound, or by causing solutions to be swallowed.

As for disorders of the stomach, such as spasmodic affections of this organ with incoercible vomiting, cocaine may sometimes render marked service. Certain perversions of the stomach, and especially boulimia, are also amenable to cocaine, as Beugnier-Corbeau has shown. It is even certain that were cocaine to be bought at a reasonably low price, so that it could be afforded, one might use it to advantage in treating the agonizing pains which attend ulcer and cancer of the stomach, and this might be done by bringing solutions of cocaine directly in contact with the lining membrane of that viscus by means of the siphon tube.

The great benefit which we have derived from the anæsthetizing properties of cocaine in painful affections of the upper part of the digestive tube, has furnished us with indications for its use in certain anal affections. Obissier was one of the first to make application of this remedy in cases of anal fissure.[1] Before effecting dilatation of the sphincter, he procured complete local anæsthesia by making at two opposite points, just at the margin of the orifice, interstitial injections of two-thirds of a grain of cocaine.

You have seen me have recourse, and successfully, to the same means, and I have been able in the case of one of our patients affected with fissure of the anus, to perform forced dilatation without pain by the help of these subcutaneous injections. These injections must be made around the sphincter, and I used in the case at which you were present, four injections of a syringeful of a four per cent. solution. Lotions do not suffice, as the unsuccessful trials of Dr. Clemente Ferreira testify.[2]

You can also have recourse to cocaine in cases of painful hemorrhoids, and you may here employ suppositories containing one-third of a grain. So much for the mucous membrane of the digestive tube; we will now pass on to that of the genito-urinary organs.

It was in this hospital that one of the first applications of cocaine to the treatment of vaginismus was made. It concerned a patient in the service of our colleague Anger, and who had not been benefited by forced dilatation under chloroform. A few swabbings with a solution of cocaine, made by my interne Lejars, rendered examination easy, and removed all pain and spasm,

[1] Lermoyez: Anæsthesia by Cocaine in Amygdalotomy, Bull. de Thér., t. cviii. p. 108.

[1] Obissier: Note on the Employment of Cocaine in Fissure of Anus, Bull. de Thér., t. cviii. p. 10.

[2] Clemente Ferreira: A case of fissure of the anus treated without success by hydrochlorate of cocaine, Bull. de Thér., t. cix. p. 216.

and thereafter made sexual approaches possible, as the husband of this woman testified some weeks afterward.[1]

Almost at the same time Cazin reported to the Society of Surgery a similar case, and since then facts have so multiplied that we may now say that if cocaine does not cure vaginismus, it at any rate greatly alleviates this painful affection in rendering sexual relations possible by the help of inunctions or lotions of this alkaloid.

Gynecology has even gone further, and by subcutaneous injections and swabbings of the neck of the womb, Doleris has maintained that we may to a certain extent mitigate the pains of childbirth.

The urethral mucous membrane is also advantageously modified by the salts of cocaine. I have derived great benefit therefrom in practising cauterization of those painful vegetations which form around the meatus urinarius in females. Guyon has employed cocaine with good effect in the male, to relieve the pain and spasm accompanying catheterism.

Finally, the respiratory and nasal mucous membranes have also derived advantage from this anæsthetic action, when it has been a case of the extraction of polypi from the nose or the application of caustic solutions to the larynx. At the same time, it is necessary to bear in mind the paralyzing action of cocaine; and in a case described by Ayssaguier, grave asphyxiating phenomena were seen to follow painting the larynx with this alkaloid. In fine, to complete the subject, I must tell you that otologists have also utilized cocaine in the treatment of affections of the ear.

To sum up, whenever you desire to obtain an anæsthesia of the skin and mucous membranes which shall be complete, temporary, and of little extent, you may utilize cocaine. Are there other substances capable of producing local anæsthesia of the tissues? This is a question which the future alone can decide. For my part I have tried caffeine, and if it diminishes the sensibility of the conjunctiva, it does this very imperfectly. It has been claimed that menthol has the same effect, but the trials which I have made with this substance have not given me any satisfactory result. Cocaine remains, then, thus far the only local anæsthetic of mucous membranes, and this fact renders the introduction of this alkaloid into medicine one of the most precious therapeutic acquisitions of this age.

Since I have spoken to you of hypnotics, allow me to finish this lecture by announcing the discovery by Dr. Bardet and myself of a powerful hypnotic.

Among the different products of the great aromatic series which we are studying at the present time, in their chemical constitution and therapeutic action, is found a mixed acetone, having for formula C_6H_5,CO,CH_3; it is *phenyl-methyl acetone*, or *aceto-phenone*. This body had been already studied by Popof and Mencki, who observed that this acetone is transformed in the economy into carbonic and benzoic acids, and eliminated by the urine in the state of hippurates.

We have found in this acetone remarkable hypnotic properties; hence we propose to substitute for its compound name the shorter appellation of *hypnone*.

Administered to the adult in the dose of from two to four drops, hypnone causes sleep, and in the insomnia determined by alcoholism its effects seem superior to those of chloral and paraldehyde.

When you inject under the skin of guinea-pigs fifty centigrammes to a gramme of hypnone in a state of purity, you determine insensibility, then a comatose state, in which the animal succumbs in the course of five or six hours. Hypnone is, as you see, a body which is liquid at the ordinary temperature, having a very strong odor which resembles that of cherry-laurel, and new-mown hay; it is not soluble in water, and therefore we have given it dissolved in glycerine and enclosed in capsules.

Our patients have not experienced any unpleasant effects from it, save always the disagreeable odor of the breath which results from the elimination of the hypnone by the lungs.

What future is in reserve for this hypnotic we do not fully know, but I thought it worth the while, in concluding, to allude to this discovery which results from researches in which most of you have participated.

HYSTERIA IN THE MALE.

BY W. PAGE McINTOSH, M.D., M.H.S.,
FORMER RESIDENT PHYSICIAN, MATERNITY HOSPITAL AND BAY VIEW ASYLUM, BALTIMORE, MD.

HYSTERIA is not susceptible of classification any more than is eclampsia or epilepsy. We must agree with Marshall Hall that it is not a feigned disease. It is real enough, but often exaggerated, and great difficulty sometimes attends the diagnosis.

In looking up the subject, I find very few cases reported in the male, especially in this country. Arnold,[1] Baily,[2] Beard,[3] Free,[4] and Smith,[5] have each reported a case in the United States. A number of cases have been reported from abroad. Not being able to classify the trouble, it is probably as well to follow Niemeyer, and place it under the head of neuroses of unknown anatomical origin.

Hysteria was supposed to be due to disturbances of the uterus, both by the ancients and by modern physicians to the time of Sydenham. It is now recognized that it may be dependent on a variety of causes with which that organ has no necessary connection.

Morbid nervous symptoms may be of considerable extent without ascertainable lesion: on the other hand, cases looking like hysteria may be organic, and thus diagnosis is made difficult. Among predisposing causes, the inheritance of a nervous system predisposed to degeneration, the so-called neuropathic diathesis, is perhaps the most prolific. Mental and physical exhaustion, fright, and the depressing influence of injury, or general disease, are the most frequent immediate causes. The trouble is most apt to occur at about the period of puberty, but neither age nor sex gives immunity. The frequency of hysteria in females and males respectively is said to be as

[4] Medical Record, 1884.
[5] Ibid., 1882.

twenty to one (this is probably incorrect, as we shall endeavor to prove), which circumstance is important as showing the uterine influence, and it definitely places hysteria in the category of nervous affections. Certain races are said to be more liable to the disease than others. In Europe, for instance, the Latins and Slavs are more prone to suffer, and in our country the negro race is peculiarly susceptible to it. Whether the negro is more susceptible from mental weakness and consequent excitable nature, or whether he has an unexplainable tendency to the disease, just as he has to tetanus, we cannot say. If we bear in mind the fact that the majority of negroes are uneducated, we are better prepared to accept the theory that the negro has inherited through generations the superstitious nature of some of the African tribes.

Occupation, or rather the want of it, is a prolific cause, and noticeable in all classes of society. We are led to believe, by prison authorities, that the vicious and depraved are more liable to paroxysms of a hysterical nature, and that among the inmates of such institutions it occasionally assumes an epidemic form.

Religious excitement exerts a similar influence. I have known as many as from twenty-five to fifty negroes of all ages and both sexes attacked in the course of an evening, during one of their "revivals." At such times a bucket of cold water brings them around very quickly.

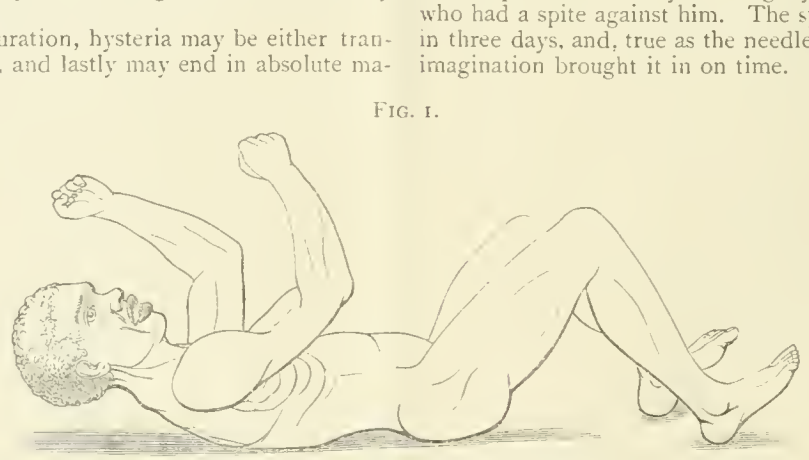
The dancing mania of the middle ages so graphically described by Hecker,[1] was, I take it, only an epidemic form of hysteria, though the author stoutly denies this.

In point of duration, hysteria may be either transient or chronic, and lastly may end in absolute mania. In the first phase it consists of an emotional explosion, and, ordinarily, at the same time the œsophagus contracts spasmodically from below upward and produces the feeling of a ball in the throat —"globus hystericus." Closely related to this, is spasmodic contraction of the diaphragm, giving pain at the pit of the stomach, spasmodic action of several groups of muscles which operate in producing complex acts, as laughing, crying, etc.; spasmodic contraction of the rima glottidis, and tension of the vocal cords, giving rise to hysterical cough; and pseudo-paralysis, in which a single extremity is involved. Hemiplegia (I have seen one such case with aphasia, in a female, lasting for months), paraplegia (I have seen one such case strongly simulating spastic spinal paralysis), and sometimes complete paralysis (Case V.) also occur.

Tendon reflexes are usually not under voluntary control, but nature seems to play tricks here also.[1]

Case I. *Violent hysteria in a male.*—Some time since, in the early fall, I was called about 4 A. M. to see Tom, a colored male, 21 years of age, stout, and previously in perfect health. He complained of intense pain in the stomach, and a few minutes after I saw him in a violent convulsion (Fig. 1). Ball of eye was fixed and turned up, muscles rigid, thumbs flexed on palms, breathing interfered with, but *glottis not closed.* Convulsion lasted a minute; he then complained of pain again; pulse 70, strong and full; temperature normal; abdomen tense; convulsion repeated in a few minutes. My first thought was strychnia poisoning, but I found on inquiry that this could not be the case, as he rested well all night. Acute indigestion and tetanus both occurred to my mind, but the absence of any wound and the clonicity of the convulsions put aside tetanus. Then I decided to treat him for cramp colic; administered a full emetic of ant. et pot. tart. and ipecac, and had him drink copiously of warm water. Nothing was ejected from the stomach except the water drunk. An injection per rectum brought away flatus and very little feces. Had another convulsion. His mind was perfectly clear, and he told me he had been "conjured" on the previous Sunday evening by an old negress who had a spite against him. The spell was to work in three days, and, true as the needle to the pole, his imagination brought it in on time.

Fig. 1.



Convulsive position; muscles in clonic contraction.

Recognizing now that I had a case of hysteria to deal with, I determined to take my time and make some observations, which I did. He had several more convulsions in the space of an hour, after which I passed a catheter and drew off about a pint of limpid urine. Ordered full dose of chloral and bromide of potassium, after which the convulsions ceased, and he slept. Ordered him ten grains of calomel to be given in a few hours.

Thursday morning, about the same hour, I was called and found him in most violent convulsions. He

[1] Humboldt Library, August, 1885.

[1] MM. P. Marie and Souza-Leite: Revue de Médecine, excerpt in Brit. Med. Journ., Aug. 22, 1885, p. 353.

had apparently done well after my visit on Wednesday. The calomel had purged him freely. I now gave him full doses of the emetics, in order to make him too sick to have convulsions. In fifteen minutes the contents of the stomach were ejected, but the convulsions continued. At this time the skin was very hyperæsthetic; the convulsions were clonic, but, at times, the muscles would remain as hard as a stone for fifteen or twenty minutes; the contour of the temporal and masseter muscles stood out in bold relief, the

FIG. 2.

Condition of opisthotonos.

angles of mouth were drawn outward, the lips apart, teeth clinched. During the convulsions he underwent very peculiar contortions, and opisthotonos developed (Fig. 2); eyes were fixed and protruding, brows wrinkled. It would occasionally require the combined strength of two men to hold him on the bed. In the interval his mind was perfectly clear, he talked rationally, laughed, sung, and prayed. He insisted that medicine would do him no good, for he was "conjured." I had resorted to the bromide of potassium, and, during the day, gave him exactly one ounce, none of which was ejected, but it failed to control the convulsions. Occasionally I anæsthetized him, which, of course, kept him quiet for the time. He had twenty-seven convulsions in twelve hours, some of which lasted half an hour.

About 5 o'clock in the evening I "suggested" to him that I would work a counter-spell and cure him. I then gave him a hypodermatic injection of morphia. He had never before seen a hypodermatic syringe, and it produced a strong mental impression. He then had only one slight convulsion, after which I repeated the injection into the arm (using very little morphia both times), and he had no more convulsions. He was well the next day, except soreness of the muscles. Occasionally he displays hysterical tendencies, but his health remains good.

CASE II.—G. M., white male, age 40 years, intelligent, educated, and no bad impulses, except a desire for women. Married, and father of six children. General nutrition good. Father, an alcoholic; one sister and one brother suffered from nerve troubles. At the time when I first saw him suffering from hysterical troubles, he was laboring under strong mental excitement; his child was dangerously ill with the croup, and I had just done a tracheotomy; the sufferings of the little one and the sight of blood were too much for him. I heard a noise, and, turning, saw him shaking and jerking, and an assistant helped him to lie down. His whole form was convulsed, and his body underwent a variety of contortions, the most peculiar of which is illustrated by Fig. 3. He had several convulsive attacks at intervals of half an hour. The trouble readily yielded to treatment.

I learned, upon inquiry, that he had had similar attacks before, and subsequently I treated him for the same trouble. At times he is free from these attacks from six months to a year, but violent excitement almost always brings them on. Sometimes he did not have attacks, but displayed the ordinary phenomena of laughing, crying, etc.

The visual field of this patient was contracted; hearing, smelling, and taste were obtunded. Hemianæsthesia to heat; the tendon reflexes were normal: he suffered occasionally from insomnia.

FIG. 3.

Convulsive position; legs and arms extended.

I saw also a brother of this man, who for two months lay in bed, making no attempt to get up, neither would he speak, but lay with eyes protruding and pupils dilated (except when asleep); he made no attempt to turn himself in bed, but would allow others to handle him without resistance. He only ate food or took medicine when it was put in his mouth. No lesion was discoverable, and he made a perfectly good recovery. This case I saw in consultation, and I believe it has been reported.

Case. III. *General hysterical hyperæsthesia in a male aged fifty years.*—I am at liberty to give only general symptoms in this case.

Other members of the family had suffered from nervous trouble. His sister was hysterical, and occasionally suffered with excessive hyperæsthesia. Patient's wife had suffered similarly, which fact seemed to make a strong mental impression on him. Personally he was strong, well built, decided tendency to obesity, had always enjoyed good health, except occasional rheumatism in ankle-joint. When I saw patient he was under treatment for felon of finger: there was apparently no other lesion, but he would complain greatly if any one touched him, and if a hand was laid upon his leg or thigh, he would yell most lustily. He kept this up several days, never being touched without hallooing. To test him, the physician in attendance and myself discussed the feasibility of applying the actual cautery to his back and feet. This conversation was conducted where he could hear it. One of us would seemingly demur, saying it would be very painful, etc.

At our next visit, twelve hours later, he allowed us to handle his limbs without complaining. Expressed himself as being much improved, and in a few days the hyperæsthesia disappeared, and he was up and went home, a distance of fifty miles. The travel on the railroad did not unpleasantly affect him.

Case IV. *Ordinary hysteria in white male, aged twenty-five years.*—I was well acquainted with the history of this young man, and knew that he had been recently disappointed in love. When I saw him he was inclined to be affectionate and wanted to embrace me. As I declined the proffered honor, he became very angry and began to cry, then to laugh; later he became very much depressed and wanted chloroform, with which to commit suicide; he tried several times to throw himself out of the window, talked incoherently, and cried and laughed constantly, had convulsive movements, but no defined aura. This, with a variety of silly acts, continued for twenty-four hours. Patient was temperate, healthy, and ordinarily intelligent.

Case V. *Complete paralysis, with aphasia in colored man, aged thirty-eight years.*—I recently saw in consultation with Dr. Pate, of this city, a man who had previously enjoyed good health. He was apparently completely paralyzed and could not talk. His pupils and tendon reflex were normal, neither hyperæsthesia nor anæsthesia present. Patient entirely recovered both voice and use of limbs in a few days, and seems to continue in good health.

The cuts were taken from life, by my brother, Dr. M. C. McIntosh, who saw the cases.

Memphis, October 15, 1885.

PRELIMINARY NOTE ON ADONIDINE.

By J. C. WILSON, M D.,
PHYSICIAN TO THE PHILADELPHIA HOSPITAL AND TO THE HOSPITAL OF THE JEFFERSON MEDICAL COLLEGE.

The *Adonis vernalis*, a plant belonging to the natural order Ranunculaceæ, and indigenous in Southern Europe, has long been empirically used in Russia in various affections, and especially in diseases of the heart. Rubnow, of St. Petersburg, in 1879, first made the medicinal properties of this plant the subject of special research. In 1882, Cervello, of Strasburg, succeeded in isolating its active principle. The results of his investigations were published in the *Archives Italliennes de Biologie*, toward the close of the same year. From this date the remedy excited much interest among the physicians of Russia and Germany. In 1884, Lesage[1] made public the results of physiological studies concerning its properties, conducted in the clinical laboratory of Germain Sée, at the Hôtel Dieu. Quite recently Durand,[2] at the suggestion of Desplats, has made a careful clinical study of the therapeutic action of this substance.

The older preparations were made from the root and leaves of adonis. Rubnow employed an infusion and maceration of the leaves, and an extract has also been used. The active principle of these preparations is the glucoside, isolated by Cervello. This substance is amorphous, colorless, without odor, intensely bitter, slightly soluble in ether and water, and freely so in alcohol. Rubnow employed the leaves in infusion of a strength of 4 to 8 parts to 180 parts of water. The dose of this preparation is a tablespoonful every two hours. Durand employed the glucoside in pills of 0.02 centigramme (one third grain) each, and rarely exceeded this dose.

The physiological effects are analogous to those of digitalis. Cervello, experimenting on frogs, found that 15 milligrammes (one-fourth grain) were sufficient permanently to arrest the heart. According to him, adonidine should be employed in a smaller dose than digitaline. The dose used by Durand is enormously greater than this. Its administration is followed by a series of phenomena which represent three well-characterized phases. First, slowing of the pulse, with elevation of the arterial pre-sure; second, increased frequency of the pulse, with still further augmentation of blood-pressure; third, still further increase of pulse-frequency, with decline of blood-pressure. Adonidine appears to be without cumulative effect. A patient of Durand's, aged 14 years, took by mistake, in the course of a few hours, 0.20 centigramme (three grains), of adonidine without serious results, other than repeated vomiting and diarrhœa. All observers agree that this remedy, while producing effects closely analogous to those of digitalis in other respects, is without cumulative dangers. Leublinski alone, among those who have used it, finds adonis badly borne, giving rise to vomiting and diarrhœa.

In addition to its action upon the heart, adonidine possesses, in a high degree, diuretic properties. Michaelis has reported a case, in which digitalis having failed to augment the volume of urine, the administration of adonis was followed by an increase of thirty per cent. Altmann, Leyden, and Riegel have also testified to its diuretic properties.[3]

Durand, as the result of careful, systematic clin-

[1] Travaux du laboratoire de clinique de M. G Sée, l'Hôtel-Dieu, Bulletin de la Société de Biologie, 1885.
[2] De l'action comparée de medicaments cardiaques, Paris, 1885.
[3] Semaine Médicale, June, 1884.

ical investigations in five cases, affirms that adonidine, in one-third grain doses, augments the arterial tension, regulates the action of the heart, diminishes the frequency of the pulse, and increases the energy of the cardiac systole. Furthermore, it rapidly induces diuresis. Its effects are prompt, it is well borne, and the indications for its employment are the same as those of digitalis, without the dangers of the latter drug.

As the result of extended comparative studies of the clinical effects of this remedy, and of those of digitalis, caffein, and convallaria, Durand concludes that, notwithstanding the dangers of digitalis, which render necessary both skill and caution in its employment, it must be assigned the first rank among cardiac stimulants; that caffein is indicated in those cases requiring a more prompt effect; and that convallaria has the advantage of producing more persistent diuresis. Convallaria is to be preferred to digitalis, where the stomach is irritable; caffein, in nervous and easily excitable individuals. Although convallaria and caffein are more prompt in their action upon the kidneys, their influence upon the heart's action is less decided than that of either digitalis or of adonidine.

These observations make more extended studies of the action of adonidine desirable. The drug is on the list of Merck, of Darmstadt, and may be had in this city of Louis Genois, apothecary. Its present price is too high to warrant its general use. But, should the observations thus far made be established, it will take permanent place among the available agents in cardiac therapeutics, and an established demand will beget a sufficient supply at reasonable prices, for the Adonis vernalis is by no means rare, its rhizome having been employed in commercial black hellebore as an adulterant, and the process by which the glucoside adonidine is extracted being not necessarily expensive. The glucoside, as at present supplied by Merck, does not in all respects correspond to the description of Durand, being of a dark brown color. In a case under the care of the writer, of old mitral insufficiency, with dilatation, feeble and irregular pulse, œdema of the legs and feet, with diminished, albuminous urine, in which digitalis could not be used, adonidine in doses of one-third of a grain, *quatuor in die*, had an excellent effect both upon the circulation and upon the action of the kidneys.

CLINICAL NOTE ON THE USE OF ANTIPYRIN.[1]

BY W. M. WELCH, M.D.,
PHYSICIAN TO THE MUNICIPAL HOSPITAL, PHILADELPHIA.

DURING the past year attention has been repeatedly called by the medical journals, both domestic and foreign, to antipyrin as an antipyretic. The credit of discovering this new drug belongs to a chemist by the name of Ludwig Knorr, an assistant in the chemical institute at Erlangen, Germany. The discovery is said to have been made synthetically, and the new product was named, chemically, dimethyl-phenyl-oxypyrazol. The name antipyrin was given to the preparation by Filehne, of Germany, who was the first to experiment with this drug and prove its antipyretic power. After it had been subjected to extensive trials in the hospitals of Germany, and received the endorsement of such men as Filehne, Huchard, Guttmann, Pribram, and some others of equal reputation, it was brought to this country, and a large number of practitioners here have already testified to its prompt and wonderful antithermic effect in various febrile and inflammatory diseases.

While Knorr bears the reputation of being a scientific chemist, he has resorted to the ordinary business expedient of an empiric, in procuring a patent for antipyrin. In palliation of this act, it is claimed that it was not his intention to place on the market a secret nostrum, but rather to secure to himself the sole right to manufacture a drug which he himself had discovered. The formula, however, is said to have been published in several languages. The specifications which were filed at the United States Patent Office, October 28, 1884, when a patent from this country was obtained, have been published by Dr. Samuel S. Adams, of Washington, in the *Journal of the American Medical Association* for December 5, 1885. But, whatever may be thought of Knorr's course in this matter, the drug is, nevertheless, of so great interest from a therapeutical standpoint as to be worthy of our attention.

Antipyrin, a faintly yellow and slightly bitter powder, somewhat resembles sulphate of cinchona in appearance and taste, and is very soluble in water. The dose recommended in nearly all of the journals is from 10 to 30 grains. This may be repeated until 60 grains shall have been taken, which amount it is not well to exceed during one day. In typhoid fever, however, it is said that much larger doses may be given with impunity. Filehne gave it in 30 grain doses, repeated every hour until 75 to 90 grains were given. It is recommended that the dose to phthisical and emaciated persons be much smaller, even as small as 2 to 4 grains, and increased if necessary. For children, one grain and a half for every year of the child's age, and repeated every hour, if required, is believed to be the proper dose.

Antipyrin is, without question, a most remarkably prompt and powerful antipyretic. It has no value as an antiperiodic. It has been especially recommended to reduce high temperature in typhoid fever, tuberculosis, and pneumonia. It has been known to cause a reduction of febrile temperature amounting to four or five degrees within two hours after its administration; and, according to some observers, the reduction continues for several hours. Dr. Huchard says that the antithermic effect is ordinarily maintained for from six to nine hours, and is sometimes perceptible on the following day. Reduction of the concomitant symptoms of high temperature, such as delirium and rapidity of pulse and respiration, does not always correspond with the degree of reduction of the temperature, though it has been asserted that such a correspondence exists.

The only unfavorable results upon which stress has been laid are occasional vomiting, and the production of an exanthematous eruption resembling

[1] Read before the Philadelphia County Medical Society, December 16, 1885.

measles. Collapse, proving fatal, is reported as having occurred in one or two instances. Some doubt, however, has been expressed as to whether the collapse in these cases was distinctly due to the drug. Be that as it may, it certainly is advisable until we know more of this agent, to exercise great caution in its use, especially in cases of cardiac weakness.

My experience in the use of antipyrin is limited to but one patient, and a single dose. Having under my care in August, of this year, a case of typhoid fever, in which the temperature continued high during the fourth week of the disease, I determined, with the consent of the consulting physician, to try antipyrin, the temperature (axillary) at that time, August 17th, being 104°, the pulse 130, and the respirations about 40. The patient was an adult female. Only 10 grains of the drug were administered in solution at 3.15 P. M., and the results were as follows:

4.15 P. M., temp. 101½°; resp. 33; pulse 125.
5.15 P. M., temp. 99⅕°; resp. 35; pulse 116.
6.15 P. M., temp. 100⅕°; resp. 36; pulse 112.
7.15 P. M., temp. 103°; resp. 31; pulse 118.

On the following day the temperature ranged between 103⅔° and 104⅕°; the respirations varied from 30 to 48, and the pulse fluctuated between 126 and 140. The patient died on the 22d, death being preceded by an increase of the nervous symptoms, incessant delirium, great tympanites, involuntary evacuations, and well-marked hemorrhage from the bowels. The temperature, on the day of dissolution, rose as high as 107½°, and at the moment of death was 106⅔°. There was no autopsy.

In this case it is seen that a single 10 grain dose of antipyrin caused a reduction of temperature in two hours amounting to four and four-fifths degrees. The concomitant symptoms (rapid pulse and respiration) did not show anything like a corresponding reduction.

While under the influence of the drug the patient's condition was very peculiar. There were restlessness and sighing, and the most profuse perspiration, I think, I have ever witnessed. The pulse was rapid, irregular, and feeble. The face and hands exhibited a peculiar pallor, and there was profound systemic depression. If there were any change in the delirium it was increased. Altogether the patient, at the end of two hours after swallowing the drug, presented such marked symptoms of approaching collapse that I became alarmed, and procured and administered as quickly as possible carbonate of ammonia and whiskey. It is proper to state that there was no nausea or vomiting.

It is evident, from the clinical history of this case, that a forced reduction of temperature in typhoid fever is not necessarily attended with the desired amelioration of the other symptoms of the disease. Nor is there, to my thinking, any reason to expect such a result, so long as the antipyretic does not change the condition or conditions upon which the fever depends. I do not wish to be understood as wholly denouncing antipyretics in diseases of high temperature, for I believe that they have a certain limited measure of usefulness; but I am of the opinion that, in the treatment of fevers of late years, too great prominence has been given to measures which combat a single symptom, and thus attention to a great extent has been directed from the morbid processes giving rise to that and the other symptoms, which, together, instead of constituting the disease, simply give expression to it. It is like attempting to remove a shadow without disturbing the substance which produces it.

My object in presenting this communication is not to speak disparagingly of antipyrin as an antipyretic, but to call attention to the fact that it may produce unfavorable and alarming symptoms, even when given in what is generally believed to be the minimum dose; and that, in large doses, there is danger of fatal collapse.

MEDICAL PROGRESS.

CHIENE'S CONTRIBUTIONS TO PRACTICAL SURGERY.—PROF. JOHN CHIENE, in an admirable series of practical notes on every-day surgery, makes, *inter alia*, the following suggestions:

In wounds of the face, the best stitch to use is horsehair. Unless the wound is of considerable size, no form of drainage is necessary. The best dressing is a pad of salicylic cotton-wool or corrosive wool, fixed in position with flexible collodion.

The introduction of the sharp spoon into surgical practice has greatly simplified the treatment of lupus. In the use of the sharp spoon, special care must be taken to scrape away the raised edges of the lupoid ulcer, as it is here that the pathological change is advancing. This is best done by scraping from the sound skin toward the centre of the ulcer. After the new formation is completely removed, the best application is a powder which has been introduced into surgical practice by Dr. Lucas Championnière, of Paris. It consists of (1) light carbonate of magnesia, which has been impregnated with the vapor of eucalyptus, (2) powdered benzoine, and (3) iodoform in equal quantities.

In persistent hemorrhage from the nasal cavity, plugging of the posterior nares should not be done until an attempt has been made to check the hemorrhage by firmly grasping the nose with the finger and thumb, so as completely to prevent any air passing through the cavity in the act of breathing. This simple means, if persistently tried, will in many cases arrest the bleeding. The hemorrhage persists because the clot, which forms at the rupture in the bloodvessel, is displaced by the air being drawn forcibly through the cavity in the attempt of the patient to clear the nostrils. If this air is prevented from passing through the cavity, the clot consolidates in position, and the hemorrhage is checked.

In the reduction of a dislocation of the lower jaw, the patient should be seated on a low stool before the surgeon. In this way the surgeon gets a sufficient leverage, standing above the patient, and the reduction of the dislocation is simplified.

In the division of a tight frænum of the tongue, when a child is tongue-tied, care must be taken not to use the scissors too freely. All that is necessary is, standing

behind the patient, to nick the anterior edge of the frænum with the scissors, and to tear with the finger-nail the remainder of the band. In this way hemorrhage, which is apt to be troublesome, is prevented.

In the removal of an elongated uvula, after you have grasped the apex of the uvula, it is to be drawn forward and rendered tense before division. If it is simply grasped, and an attempt made to divide it in its normal position, it is not always an easy matter to effect the object desired. When it is rendered tense the operation is a very simple one.—*Edinburgh Medical Journal*, Dec. 1885.

NERVE-STRETCHING.—CHAUVEL, in a recent *résumé* of our existing knowledge of effects of nerve-stretching, and the indications for this procedure, maintains that, although the physiological aspects of this treatment are but imperfectly understood, the operation itself is one which should take rank in surgery beside the section and resection of nerves. It is indicated:

1. In rebellious peripheral neuralgias; and is here preferable to all ordinary treatments.
2. In contractures and in peripheral paralyses, especially of traumatic origin.
3. In the anæsthesia of leprosy.

Its efficacy is more than doubtful in tetanus, in locomotor ataxia, and in affections of the medulla. Its use should apparently be abandoned in all cases of atrophy of the optic nerve, of whatever nature or degree.—*L'Abeille Médicale*, Nov. 30, 1885.

STRYCHNIA IN ACUTE ALCOHOLISM.—DR. LARDIER has long employed strychnia in the treatment of delirium tremens, and regards it as the best remedy which we possess for this condition—as, in fact, a veritable specific. He insists upon the necessity of giving the drug in large doses. In one case he had given granules containing each $\frac{1}{18}$ grain every two hours for several days without any appreciable result. He then increased the number of granules and also administered the drug hypodermatically, giving in all $1\frac{2}{3}$ grains in the space of twenty-three hours. The result was a most happy one. The patient soon fell into a refreshing sleep, never exhibiting the slightest symptom of strychnia poisoning.—*The Practitioner*, Dec. 1885.

CARBON DISULPHIDE IN NEURALGIA.—GUERDEN recommends, as far superior to the menthol pencil in neuralgia, the application, for three minutes, of:

Carbon disulphide (rectified)	9 parts.
Essence of mint	1 part.

Shake well.

In superficial neuralgias, whether facial, dental, or intercostal, and in superficial rheumatic pains, this application produces instantaneous relief, and not unfrequently a cure. In the deep neuralgias, as sciatica, it is necessary to project the solution upon the painful part by means of an atomizer. Actual freezing of the skin is unnecessary. Dental neuralgia usually succumbs to this treatment applied to the corresponding cheek—a slight application to the gum, or the insertion into the carious tooth of a pledget of cotton moistened with the solution being occasionally advisable. Very obstinate facial, dental, and pharyngeal neuralgias may be subdued by gently introducing into the external auditory meatus a pledget thus moistened, squeezed out, and covered by a layer of dry cotton.—*Revue de Thérapeutique*, Dec. 1, 1885.

VAGINAL DRAINAGE IN THE TREATMENT OF UTERINE CANCER, AS A MEANS OF PREVENTING THE DEVELOPMENT OF THE CHARACTERISTIC ODOR.—WYMAN states that in those of his cases of uterine cancer in which arrangement has been made for the drainage of the vaginal fluid, there appears a marked improvement, both as regards the health of the patient and the abatement of the offensive odor characteristic of the disease.

One would, on first thought, regard the vagina as sufficiently patulous to permit the ready exit of any contained fluid, but it is found, clinically, that considerable quantities of fluid often escape from the vagina during a digital examination, even though the patient has been standing or walking for several hours. Wyman, therefore, recommends the constant retention in the vagina, in these cases, of a tube, which shall keep the vaginal orifice open and the fourchette sufficiently low to permit the removal by gravity of the offensive secretions, which, on their escape, are collected by absorbent cotton, which is frequently burnt and replaced.—*The Medical Age*, Nov. 25, 1885.

MORRHUOL, THE SUPPOSED ACTIVE PRINCIPLE OF COD-LIVER OIL.—By the evaporation of an alcoholic extract of cod-liver oil, CHAPOTEAUT has produced a substance for which are claimed all the active virtues of the original oil, the bulk of which is but one-twenty-fifth that of the latter.

According to TAPAGE, this extract is quite efficacious in the first stage of phthisis, and can be taken for months in large doses without occasioning digestive disturbances. It is well borne by infants, and has been used with good results in strumous and rachitic conditions.

Its chemical constitution is quite complex, consisting in large part of phosphorus, iodine, and bromine, apparently in organic combination.—*L'Union Médicale*, Dec. 5, 1885.

THE DANGERS OF COCAINE.—DR. HODGES, of the Leicester Infirmary, writes as follows to the London *Lancet* of December 12, 1885: Professor Hirschberg, of Berlin, (whose admirable clinic I have lately visited) uses cocaine dissolved in solution of perchloride of mercury (1 in 5000), and has had no cases of septic inflammation following its use. To the list of disastrous cases recorded by Mr. Nettleship, Dr. Bell Taylor, and others, I have one to add, which occurred when I was using the ordinary solution of cocaine in distilled water.

TURPETH MINERAL IN SYPHILIS.—As a local application in certain syphilitic affections of the skin, MAURIAC advises the use of the following pomade:

Turpeth mineral	2–3 parts.
Lard	30 parts.

This is applied in the various impetiginous eruptions of the hairy portions of the skin, and to the persistent spots on the face, hands, and wrists, and is gently rubbed for five minutes up to the point of slight irritation. In the same manner are treated the minute

papules of the nasal alæ, of the labiomental fold, and of the labial commissure.—*L'Union Médicale*, Dec. 12, 1885.

Heredity in Bright's Disease.—Baudet published some time ago a study of three cases of nephritis occurring in the same family, from which he was led to the belief that the disease might in certain cases be hereditary. This hypothesis has received a certain measure of confirmation from another series of cases published by Kidd (*Ann. de la Société de Méd. d'Anvers*, 1885), in which, out of the twelve children of a female suffering from Bright's disease, seven died of the same malady.—*Florida Med. and Surg. Journ.*, Dec. 1885.

The Relation Between Inflammation of the Gums and Disease Elsewhere.—The origin of the various skin eruptions, vomiting, convulsions, diarrhœa, and constipation, so frequently found to be coincident with the process of dentition in children, is, in the opinion of Kaczorowski, to be sought less in the condition of the teeth than in that of the gums. The author, impressed with the idea that the essence of most inflammatory processes consists in an infection by microparasites, proceeded to treat the swollen gums and cavity of the mouth with a solution of tincture of iodine in common salt (chloride of sodium, 1 per cent.; tr. iod., 0.5 per cent.). A half to a teaspoonful of this solution, according to the age of the child, is applied every quarter or half hour. He found that, simultaneously with the paling of the gums, the concomitant catarrh of the respiratory and digestive mucous membranes, the feverishness, and reflex nervous phenomena came to an end, without the use of other means than a simple purgative. Further observations of this connection between diseases of the gums and other affections, led the author to apply the same treatment to adults. That the cavity of the mouth, which is the great entrance gate through which organisms find their way into the body, should be first attacked by them is not surprising; swollen gums form a suitable nidus for their development. A receptive state of the mouth is produced in children by the mechanical injury done to the gums by hard teething rings, and in adults by artificial teeth, plates, and the like, and by chemical substances. But the greatest share in the process is played by the teeth. They irritate mechanically when they are decayed, chemically when they are foul, and functionally during their eruption.—*Manchester Medical Chronicle*, December, 1885.

Salicylate of Soda in the Treatment of Confluent Variola.—At a recent meeting of the Bordeaux Medical and Surgical Society, M. Saint-Philippe presented a report on the use of sodium salicylate in sixty cases of variola. Under the influence of this antithermic and germicidal agent, he has observed fall of temperature and diminution in the frequency of the pulse, the reappearance of calmness, appetite, and sleep. The pathological action of the skin is modified, and on the twelfth or thirteenth day the pustules become dry. It is given from the first appearance of the eruption, in syrup, in doses of 90–120 grains for an adult, and 60–90 grains for an infant. The only observed ill-effect is a temporary anorexia. Cutaneous lotions of the salicylate in ten per cent. solution, rapidly abort the pustules, but may be followed by numerous extremely painful abscesses.—*L'Union Médicale*, Dec. 12, 1885.

Influence of Acute Febrile Diseases on Pregnancy.—Hofmeier (*Zeitschrift f. Geb. und Gyn.*, XI. 2) formulates as follows our present knowledge of this subject:

The gravida, when an acute febrile disease is superadded to her condition, is not more endangered than is a non-gravida affected by the same disease; except when the fœtus, in consequence of the mother's sickness, dies, and abortion or premature labor occurs during the course of the febrile disease. Rarely will the life of the fœtus be endangered through the sickness of the mother. Variola is the best known exception to this statement. It is the rule, however, that the fœtus rarely dies directly from the acute disease affecting the mother. Its death, when it occurs, is probably rather due to the effects of the maternal high temperature. A further cause, according to Slavjansky, applicable especially to cholera, is the occurrence of a metritis decidua hemorrhagica.

As a contribution to this subject, Hofmeier reports two very carefully observed cases. The one concerns a patient of twenty-seven, mother of four children, five months pregnant, who convalesced well from a severe pneumonia, went to term, and was delivered of a healthy seven-pound fœtus. This case tallies with the conclusion reached by Ricau, who found that pneumonia, attacking a patient less than 180 days gravid, was not especially dangerous to either mother or child. His figures are: of 28 cases of pneumonia, in patients gravid less than 180 days, 23 recovered (6 miscarried, 17 did not, and 5 died); whilst of 15 cases beyond 180 days, 8 recovered (5 with and 3 without miscarriage), and 7 died. The second case is of erysipelas migrans during pregnancy, and Hofmeier could not find a parallel case in literature. The case is further interesting from the observations made as to the effect of the maternal temperature on the fœtal pulse, as shown in the annexed table:

Mother's temperature.	Fœtal heart.
40.5° C. = 105° F.	180.
40° C. = 104° F.	160.
38° C. = 100° F.	140.
37.5° C. = 99° F.	132.

The patient was at the end of pregnancy, did not abort, but at the end of the fever gave birth to a healthy fœtus, with no sign of desquamation. The patient's lying-in period was in every way favorable, and this in spite of the belief in the homogeneity of the erysipelas and puerperal fever coccus. The patient was delivered in the same bed and ward in which she lay sick with erysipelas, and an abscess over the sacrum (the result of erysipelas) was still discharging pus.—*American Journal of Obstetrics*, Dec. 1885.

Salix Nigra as a Sexual Sedative.—Dr. F. T. Paine, in the *Report of the Texas State Medical Society for 1885*, records the successful use of a fluid extract of Salix nigra (aments), or floral buds of the common Southern willow tree, in numerous cases of sexual erethism.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 2, 1886.

THE COLD BATH IN TYPHOID FEVER.

THE question of the utility of the cold bath in typhoid fever is not yet settled, even in Germany, where the brilliant statistics of Brand and Liebermeister have resulted in the introduction of hydrotherapy into most of the large hospitals. As a routine measure, the system has not found favor in the eyes of English and American physicians, among whom Cayley, at the London Fever Hospital, seems to have been the only one who has tested the plan on a very large scale.

In the *Berliner klinische Wochenschrift*, Nos. 45 and 46, 1885, SENATOR discusses the cold-water treatment, and brings forward evidence to show that equally good results may be obtained without it. Undoubtedly during the past twenty years, since the introduction of hydrotherapy, the mortality from typhoid fever has been greatly reduced in German hospitals, but statistics comparing this with previous periods are manifestly unfair. Other important conditions must be taken into consideration, such as the nursing, the attention to diet, and the general hygienic surroundings, and to the improvement in these Senator is inclined to attribute an important share in the reduction of the death rate. Gläser's statistics from the Hamburg General Hospital, for 1874–77, show the same mortality, 7.2 per cent., in 937 typhoid patients treated by the ordinary methods, and 868 patients subjected to the cold bath.

As a further contribution to the solution of the question, Senator has instituted a comparison between the results of the treatment of typhoid cases in the eight large hospitals of Berlin, for the ten years 1875–84. Of these he excludes three, the Charité and the two city hospitals—Friedrichshain and Moabit, as the patients admitted to them are from the very poorest classes; while in the Hedwig's, Elizabeth, Lazarus, Bethanien, and Augusta hospitals the conditions are very similar, and the patients are drawn from the better classes of the poor. In the three large hospitals, the Charité, Friedrichshain, and Moabit, the average mortality of typhoid cases for the ten years was 16.4 per cent., 19.6 per cent., and 15.2 per cent., respectively. In the others, which are smaller institutions, the death-rate was considerably lower, as shown by the following figures: Hedwig's, 14.7 per cent.; Elizabeth, 12.8 per cent.; Lazarus, 14.1 per cent.; Bethanien, 13.5 per cent.; and Augusta, 12.3 per cent. In the last named institution, Senator has charge of the medical wards, and he takes pains to show that the low mortality is not due to any favoring conditions of age, sex, or rank of the patients. As regards treatment, he has followed an expectant or symptomatic plan, while in the other four hospitals the cold bath has been used to a greater or less degree; in none, perhaps, to the extent which Brand directed, though in the Bethanien, the system has been quite thoroughly enforced.

A comparison of the statistics of the five hospitals shows that the percentage of recoveries "has not been essentially influenced by the different special treatments in vogue." At the Augusta Hospital, no regular antipyretic method is employed; that is to say, the patient does not receive antipyretic treatment when the fever reaches a certain height, but the indication is always drawn from the general condition. The fever has not, as a symptom, the significance that Liebermeister and others suppose, and the changes in the nutrition of the organs do not depend on the high temperature alone. A study of tetanus teaches us that high temperature and the febrile process are two different things. Senator is not opposed to the cold bath; he believes that it has its uses, but as an antipyretic he places it far below quinine or antipyrin, which have also the advantage of being antiparasitic remedies. The bath does good, not so much by reducing the fever as by its action upon the nervous system: under its use the patient's mind becomes clearer and brighter; and another beneficial effect is upon the circulation and respiration, to both of which it is a powerful stimulus. If a rule is to be adopted, it should be that the cold bath is specially indicated in those cases with fever, stupor, and mental dulness—the febris nervosa stupida of the old writers. Statistics show very clearly that hemorrhage from the bowels is more likely to occur in this cold method of treatment, and that relapses are not more frequent.

In the discussion which followed the reading of Senator's paper at the Berlin Medical Society, GOLTDAMMER, of the Bethanien, spoke of the difficulty of forming a clear judgment concerning therapeutic measures in typhoid fever. So many factors have to

be considered, of which the treatment is, perhaps, not the most important. The nursing, the relative proportion of light and severe cases, and the time of entrance into the hospital influence the mortality to a very great degree. Thus, of the 3600 typhoid patients treated in the Bethanien during 17 years, the total mortality was only 12.8 per cent., but of the patients admitted in the third week, or later, the death-rate was 36 per cent. Goltdammer referred to the statistics of the Prussian army as illustrating the value of the cold bath in typhoid fever. Prior to 1865, the death-rate from this disease ranged from 20 to 25 per cent., but for the past nine years the mortality has been only 10.1 per cent. In the other European armies Brand's system is not fully carried out, and the death-rate still remains high, being 25 per cent. in the Austrian army, 28 to 36 per cent. in the Italian, and 36.5 per cent. in the French.

In hospital practice, the truth would seem to be that of 100 typhoid patients 75 will do well with careful nursing; of the remaining 25, from 10 to 15 will die under any method of treatment, while the fate of the remainder will depend very much on the skill with which the physician handles the therapeutic means at his disposal, of which, in certain cases, the cold bath is one of the most valuable.

THE LAST LYONS FORCEPS.

Probably about a hundred years after the invention of the obstetric forceps by the senior Dr. Peter Chamberlen, Jean Palfyn, in 1723, presented to the Paris Academy of Sciences his obstetric forceps with parallel blades, and the instrument became known as the Hands of Palfyn. But about this time a knowledge of the Chamberlen instrument, so long kept secret by the inventor and by his family, became general, and for nearly a hundred years various modifications of this forceps, with handles crossing and locking, were made, while no important change was made in that invented by Palfyn, the idea involved in it being for a long time entirely lost sight of.

In the early part of the present century, however, Thenance invented a forceps with parallel branches, an instrument which, according to Tarnier, is still very much employed in a part of France, and is known by the name of the "*forceps Lyonnais.*" Valette, of Lyons, also devised a forceps in which the branches were parallel instead of crossing. Another instrument, similar as to the branches being parallel, was the leniceps of Mattei. The inventor, accepting the derivation which most obstetricians have given of the word forceps, viz., *fortiter capiens*, seizing strongly, called his instrument *leniter capiens*, seizing gently. Here, by the way, is an error which it is worth while to correct. The use of the word forceps by the Latin poets, Virgil and Ovid, for example, points very clearly to the fact that they meant by this term an instrument for seizing hot metal, and, therefore, the derivation is from *formus* hot, and *capiens*, or *capere*. Chereau has also shown that Festus used the word *formucapes* as a synonym for *forcipes*, the plural of forceps.

Following the examples of Thenance and Valette, Chassagny, of Lyons, whose method of applying mechanical traction to the forceps is so well known to obstetricians, and so generally rejected by them, has recently shown at Paris a new forceps of his device with parallel branches, and thus we have another Lyonnaise forceps.

A description with a woodcut of this forceps is given in *L'Union Médicale* of November 21st. The part of the branch applied to the fœtal head has the usual ellipse form, and also the pelvic curve, but the branches, after the formation of this part, instead of crossing in order to form the articulation, change their direction, diverging to the right and to the left, and at the end the handles are about six inches apart, but articulate by means of a cross-bar. Chassagny holds that the crossed forceps makes, at the end of the blades, an open V, the apex of this triangle being at the articulation, while in his instrument the blades form an inverted Λ, with its summit at the ends of the blades. Now, when the fœtal head enters the V of the crossed forceps, the blades being rather deep in the pelvis, the sides of the inferior part of the ellipse cannot be brought closer without slipping until the ends of the blades are spread out like a fan, and there is gliding caused by pressure. As the size of the fœtal head increases, this gliding becomes greater, and the head enters proportionately less in the ellipse. Hence, this forceps is least adapted for the delivery of the head the more it is needed, for large heads are a frequent source of dystocia.

On the other hand, the branches of the new forceps, either in withdrawing from, or approaching to each other, always remain nearly perfectly parallel.

The pressure which the crossed forceps exerts upon the head is always oblique, from below upward, and drives the head further toward the points of the blades, where it is arrested by the increased curvature of the latter; in spite of firmly grasping the handles, this gliding occurs when traction is made, and then the middle part of the blades is separated from the head, which is held only by their ends.

The new forceps, according to Chassagny, holds the head more firmly, less pressure is required, and its blades, embracing a greater extent of surface, are less likely to do injury.

Experiments made with the two forceps, in the delivery of an artificial head through a pelvis, with each of its diameters lessened about four-tenths of an inch, showed that more than twice as much force

was required with the crossed forceps to extract the head than when the extraction was made with Chassagny's instrument.

The author states that these theoretical views, as well as experimental proofs, are fully confirmed by many cases in practice. In all the applications of the forceps, even in those terminated by considerable manual or mechanical traction, the instrument leaves but insignificant or transitory traces upon the head of the infant. These traces are at their maximum on the parts of the head corresponding to the middle part of the blades, and at their minimum, or entirely absent, at those parts corresponding with the ends of the blades.

It is hardly necessary to state to those who know his views as to the importance of mechanical traction in forceps delivery, that the woodcut of his new instrument shows places for the attachment of traction cords.

Velpeau once remarked, half in jest, we think, that when a man did not know how to use the old forceps, he invented a new one. This criticism cannot, however, be applied to Chassagny, whose ability and fame as an obstetrician are great. Whether his new instrument will prove an important contribution to obstetric progress, time and a larger experience must decide.

ANALGESIA FROM LOCAL IRRITATION.

SEVERAL years ago, Brown-Séquard discovered that a more or less complete analgesia of all parts of the body could be induced by stimulating the mucous membrane of the larynx, and he showed, moreover, that the phenomenon was the result of an inhibition influence upon the nerve centres, conveyed through the superior laryngeal nerve, and that it could be produced either on the whole body or upon only one side.

He has recently communicated to the Academy of Sciences of Paris the results of additional investigations on the subject, made chiefly upon dogs and donkeys, in which latter animals the condition is readily induced and is long continued. The mucous membrane of the larynx is the region in which stimulation is most certain to be followed by analgesia. The best stimuli are chloroform and carbolic acid, but the vapor of the former must not be allowed to reach the lungs. Twelve or fifteen drops of a ten per cent. solution of cocaine, injected into the mucous membrane, produce the same effect. Other less effectual means are galvanization of the superior laryngeal nerves, cauterization of the mucosa, the insertion of a tube or the finger in the larynx, tracheotomy, or a simple incision in the skin of the neck. This laryngeal irritation will sometimes produce such absolute analgesia that large nerve trunks may be cut, deep cauterization made, or the strongest galvanic currents applied without causing in the animal any signs of pain. The tactile sensation remains, and the muscle sense is not affected. The effects are best produced in animals after tracheotomy, as the larynx can then be manipulated freely and there is no danger of the chloroform vapor or the carbolic acid reaching the lungs.

It is difficult to induce similar effects in man, but Brown-Séquard has succeeded, by causing a person to inhale pure air the first two-thirds of the inspiratory act and carbolic acid vapor during the remaining third. At first the glottis closes during the inhalation, but the sensibility of the mucous membrane gradually diminishes and the vapor can then be readily inspired. Sometimes the analgesic effects are rapid, but the inhalation must be kept up, as a rule, for at least twenty minutes. The duration of the analgesia may be forty hours, and for so long a period as two days there may be complete abolition of pains produced by various causes.

We trust that these remarkable results will be confirmed, for they seem to indicate a wide range of usefulness for this curious inhibition effect, if we can secure a convenient and harmless mode of irritating the terminal filaments of the superior laryngeal nerves.

IODAL AND IODOL.

BELIEVING that iodal would be a useful substitute for iodoform as a local application, that it would be free from the disagreeable odor of the latter, and that it would have a very decided anæsthetic effect, we have endeavored for more than a year to obtain it for trial. A few weeks ago we received from a drug importing house a substance marked iodol, which at first we supposed to be that which we had sought, only having a new name. The mistake, however, was soon discovered, for iodol proved to be a new substance first made by DRS. SILBER and CIMAICIAN, of Rome; chemically it is tetra-iodo-pyrrhol, and this has been abbreviated into iodol.

According to experiments made by DR. MAZZONI, of Rome, iodol is a powerful antiseptic, having an anæsthetic action, and greatly promoting the granulation of wounds. It contains nearly ninety per cent. of iodine, or about seven per cent. less than iodoform. One of the obstacles to its use is its sparing solubility, and another is its very high price, an ounce costing between two and three dollars, though it is most probable, should there be any considerable demand, it could be had for very much less than is now asked for it. The results obtained with iodol by Mazzoni have been stated in a recent number of THE NEWS.

The first and only reference to any experiment with iodal we have met may be found in the *Gazette Hebdomadaire*, for October 22, 1869. RABUTEAU pre-

pared iodal by treating iodine with a mixture of nitric acid and alcohol; he found that it was decomposed under the influence of bases, as are bromal and chloral, giving iodoform and a formiate. He injected about ninety grains into the rectum of a dog; the animal was anæsthetized, but it had convulsions, and died.

It seems remarkable that no further investigations as to the action of iodal have been made, for it is not improbable that this substance will prove to be a valuable antiseptic as well as local anæsthetic, and that it possibly may be successfully administered internally for its alterative influence, or for the purpose of producing absorption.

REVIEWS.

A MANUAL OF MICROSCOPICAL TECHNOLOGY FOR USE IN INVESTIGATIONS OF MEDICINE AND PATHOLOGICAL ANATOMY. By DR. CARL FRIEDLÄNDER, Lecturer on Pathological Anatomy in the University of Berlin. Translated, with the express permission of the author, from the second edition, by STEPHEN YATES HOWELL, M.D., of Buffalo, N. Y. New York: G. P. Putnam's Sons, 1885.

DR. HOWELL has done good service in giving to the profession a translation of this excellent manual, which is deservedly very popular in Germany. Friedländer is the pathologist at one of the large city hospitals of Berlin, and an expert in all departments of medical microscopy. The work is specially designed for students and practitioners, and contains full instruction on the details of section cutting, staining of bacteria, and the examination of the various tissues and discharges. The section on the detection and examination of microörganisms will be found of special value. On the subject of uterine and vaginal discharges, the remarks are particularly good, and the question of the diagnosis of carcinoma, adenoma, and erosion, by the examination of pieces of tissue, is very fully discussed. An intimate acquaintance with the first and second editions enables us to speak very positively of the merits of this manual as a reliable, practical guide, and the student will find in it a comprehensive exposition of the recent improvements in the field of pathological investigation.

The translator has done his work very well. He has added a section on the cholera bacillus, in which the four pages on the culture of this organism are quite superfluous. The absence of an index in the original is no excuse for the omission of it in a translation.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

SECTION OF SURGERY.

Stated Meeting, December 14, 1885.

THE CHAIRMAN, STEPHEN SMITH, M.D., IN THE CHAIR.

THE CHAIRMAN said, in introducing the

DISCUSSION ON THE INDICATIONS FOR LAPAROTOMY IN PENETRATING STAB AND SHOT WOUNDS OF THE ABDOMINAL CAVITY,

that in these cases the old method among surgeons was to watch indications, and treat the injuries as ordinary wounds, without any operative interference. Recently, however, laparotomy has been performed successfully in so many conditions and by so many operators in this and other countries that it is a matter of importance to determine how far this procedure is applicable in the class of cases constituting the present subject of discussion. To what extent laparotomy is now resorted to in hospital practice in this city for penetrating wounds of the abdomen was made apparent in the course of the remarks of the various well-known surgeons present.

DR. JOSEPH D. BRYANT claimed that laparotomy should be performed in all cases immediately after the accident, and this statement embodies the portion of the important subject under consideration on the present occasion, which had been allotted to him as chairman. He was unwilling, however, to subscribe himself as an advocate, in the full sense of the term, of any assertion so nearly approaching dogmatism, especially when made in connection with a means of treatment which cannot as yet be said to meet the approval of the profession at large. He who unconditionally asserts that any operation or method of procedure should be resorted to in all cases, even though it is a measure accepted by the profession generally, takes a position that requires, in justice to the profession and the patient, that all operators shall be competent and well armed for its performance. Especially is conservatism necessary in the advocacy of an operation the propriety of which, as yet, is spoken of by many with doubt commingled with dread.

But a short time has elapsed since the late Prof. James R. Wood, in this hall, opposed the measure on what appeared at that time to be sound, practical principles. At least, his remarks received the general approval of the profession not only in this but in foreign countries, and although marked advancement in all surgical procedures has taken place since then, a sufficient time has not yet elapsed, nor are the members of the profession well enough informed on the details of the entire operation, for any one to proclaim boldly "laparotomy in all cases." Few, indeed, are the hospitals in the city of New York which can "immediately after the accident," in the accepted sense of the term, offer the recognized theoretical and many of the practical facilities necessary to dispatch and cleanliness in operating, not to mention other influences bearing on the success of the operation. If these facts are true, how much more illy prepared for the performance of laparotomy *in any case* will the patient find the members composing the great mass of the profession?

He thought it generally conceded that when a member of the profession reads a paper, or makes remarks, or takes part in such a discussion as this, he addresses himself not only to those who may be present at the meeting, but also to all others who may come to read the report of the proceedings afterward. Therefore, for the speakers to-night to place themselves on record as exponents of a method of procedure that even in the majority of the great hospitals, many of them as yet scarcely, if at all, able to meet the entire demands of the case, is to commend to their less fortunate brethren a means that may prove derogatory to their professional reputations, and also relegate this now promising method to the solitude from which it is but slowly emerging.

Dr. Bryant then went on to say that he would change

somewhat the dogmatic statement with which he commenced by putting it into the form of an interrogatory, so that it should read, "Should laparotomy be performed in all cases immediately after the accident?" This interrogatory can then be considered practically as made up of three divisions: *First*, Shall laparotomy be performed in any case? *Second*, Shall it be performed in all cases? *Third*, When contemplated, shall it be done immediately after the accident?

Shall laparotomy be performed in any case? It cannot be denied that laparotomy in connection with various abdominal growths is a fully established operation, and that the results attending the invasion of the abdominal cavity by the numerous operators of this and of foreign countries, plainly attest the expediency of the measure in connection with such growths. Still, there has been a time within the easy recollection of many when even the now popular measure of ovariotomy was less favored than is now the subject of the present discussion. There is, so far as I am aware, no proof of the fact that the peritoneum of the male is not as tolerant of manipulations as is that of the female. The excellent success of Billroth, Rydygier, and many others, so far as immediate results are concerned, from operations on the stomach, pylorus, gall-bladder, spleen, kidneys, etc., of both sexes fully attest that intolerance of the peritoneum to manipulations cannot be considered a rational objection to the operation of laparotomy for penetrating abdominal wounds. The time occupied in the performance of many of the successful operations on the structures referred to is greater than that required to perform laparotomy for a penetrating wound in its entirety, therefore the length of time required cannot be urged as a rational objection to the measure. The extent of the raw surfaces made in many of the successful operations on the stomach, pylorus, etc., is far greater than can well occur in connection with laparotomy for penetrating wounds.

Among the practical elements that at the present time enter into a case of laparotomy for penetrating wounds, but which do not exist, or exert an equal force, in laparotomy for other common causes, are the following:

A. A doubt whether the abdominal viscera be injured. This doubt can exert but little influence, since the signs and symptoms of visceral penetration are as pronounced as those relating to other conditions in which laparotomy is deemed advisable. Moreover, an exploratory laparotomy enables the operator to settle the question of penetration, as it has often before settled matters of doubt in other conditions calling for this operation.

B. Existing shock. This element is almost entirely limited to those cases of laparotomy which are to be done for penetrating wounds. The shock is due either to loss of blood, to injury done the parts, or to both combined. Slight shock always attends penetrating wounds of the abdomen that involve the viscera. We believe it to be an established fact, however, that when severe shock follows immediately after the injury, it is due in the great majority of cases to loss of blood; and if it is due to loss of blood, the hemorrhage should be checked at once. An exploratory laparotomy will decide this question.

C. Unfavorable surroundings of the patient. This element too, like the second, is limited to a laparotomy for penetrating wounds, and refers, of course, to the surroundings of the patient and the time of the injury, the removal to his home or to a hospital, and also to the absence of proper preparations to operate in accordance with the best recognized methods of procedure in such cases; none of which are likely to occur in a laparotomy for other common causes. It is impossible entirely to avoid these contingencies, but their dangers can be greatly lessened by caution in moving the patient; by taking him to a suitable hospital instead of his own home, and by increased familiarity, on the part of the profession, with all the details pertaining to the operation of laparotomy in such cases.

D. Unskilled operators. By this, Dr. Bryant said he meant that the surgeon in charge of the case might not have had his attention forcibly drawn to the details of the operation which are recognized as having an important bearing on the prognosis of such cases. More particularly would he find himself in this position if he had previously looked on the operation with a disfavor bred of prejudice, instead of the result of patient toil and observation. This element can be entirely overcome if the members of the profession will devote an ordinary amount of attention to the matter.

E. Greater exposure of the abdominal cavity and its contents. The great caution necessary in order to find out and to remove from the abdominal cavity all the blood and exuded intestinal contents, to check hemorrhage, and also to detect all points of injury, require that the intestines and the omentum should be thoroughly examined by a preconceived method, rather than by the rough jostling associated with illogical haste. The time employed and the exposure incurred in removing intestinal extravasations, in seeking for and repairing the points of injury, are not useless if the task be performed with proper dispatch, since these procedures offer the only means of saving the patient's life. The time occupied by them in laparotomy for penetrating wounds cannot be greater, under proper surroundings, than that occupied in the performance of many of the successful operations upon the stomach, duodenum, etc.; yet, without doubt, a greater surface of peritoneum is manipulated in the latter, and the peritoneum is also longer exposed to external influences. Can the presumptively unfavorable influence on the case arising from these reasons be lessened or obviated? This question, Dr. Bryant said, he could answer in the affirmative; but since its consideration more properly belonged under the head of the treatment, it could not claim a place in his present remarks.

F. Existence of hemorrhage. In visceral perforation intra-abdominal hemorrhage is necessarily a constant feature. The amount of blood lost depends, of course, largely on the size and the number of the vessels injured. The vessels of the omentum and of the intestines, especially the former, bleed with a pertinacity which is unusual in all other portions of the body, owing, it is thought, to the walls of the vessels being loosely supported by the surrounding tissues; also, to the fact that they seem to possess in a much less degree the inherent attributes which ordinarily enable the natural forces of a vessel to check hemorrhage, viz., contraction and retraction. The suspicion of the existence of much intra-abdominal hemorrhage is enough to

indicate the making, at least, of an exploratory incision, by which means its existence could be quite positively diagnosticated; when, if necessary, the incision can be extended, bleeding points checked, and blood-clots removed.

G. Extravasation of intestinal contents. This is a part of the history of penetrating abdominal wounds, and constitutes the occurrence which is most dreaded by the surgeon. The late Dr. Gross asserted that no case had ever been known to recover in which fecal matter was present in the peritoneal cavity; therefore, this condition is the strongest of the indications calling for laparotomy, offering, as it does, the only means of recovery.

H. The greater difficulty of cleansing the abdominal cavity. If blood and intestinal contents have been generally diffused, the cleansing of the abdominal cavity is more tedious and difficult, and also of greater importance, than in laparotomy for other causes; but the thorough performance of this duty, at least so far as the intestinal contents are concerned, appears to be the only means of saving the life of the patient. As to blood, no one can tell the amount that might remain, and yet recovery occur.

In Dr. Bryant's opinion, laparotomy is a justifiable operation; but it is not to be attempted, even in so-called favorable cases, unless the operator can avail himself of many of the recognized means of procedure necessary to control the shock of the operation, and is sufficiently familiar with its steps to accomplish the work with accuracy and dispatch.

As to the second interrogatory, *Shall laparotomy be performed in all cases?* this portion of the subject had been allotted to others for discussion, and consequently he said he would pass on at once to the third question.

When contemplated, shall laparotomy be done immediately after the accident? Assuming all things to be equal, it should be done at once; that is, as soon as the necessary preparations required to insure a fair prospect of success could be made. In his opinion, laparotomy for penetrating wounds of the abdomen should be of two kinds: the exploratory and the actual. In the former an incision is made in the median line, so situated and of sufficient length, to expose to view the probable seat of the internal injury; which will enable the surgeon to settle not a few important and perplexing questions. He can then, in the great majority of instances, determine if penetration of a viscus has occurred, if hemorrhage is taking place, and if intestinal extravasation exists. Among the common causes of death from abdominal wounds may be mentioned, hemorrhage, peritonitis, septicæmia, exhaustion, etc. If the patient be in danger from immediate hemorrhage, the blood in the abdominal cavity can be seen through the incision in the abdominal walls. If any considerable amount of blood or of the intestinal contents exists in the peritoneal cavity, peritonitis and death will surely ensue; and these conditions can be observed through the opening. Blood in the peritoneal cavity may cause septicæmia, and that rapidly; its decomposition being hastened by the presence of escaped intestinal gases. This, too, may be seen, as its presence is easily detected by carefully raising the omentum and pushing aside the intestines in the line of the injury.

Does the exploratory incision expose the patient to unusual danger? Dr. Bryant thought not. It seemed to him that the large number of laparotomies which have been done here and abroad, and the good results attending them, especially those of Mr. Tait in England, answer this question in the negative. If this conclusion be true, all is gained that is possible, while but little can be lost from the exploratory incision; for if the conditions observed call for it, the actual laparotomy in its entirety can be done at once.

Dr. J. Williston Wright said that he was not prepared to take the ground that all cases of penetrating wounds of the abdomen are to be treated by laparotomy. If gunshot wounds be considered, it will be found that the large or small size of the missile in any instance makes a great difference in the severity of the injury. The velocity of the missile also constitutes an important element in the gravity of the case. For example, he did not believe that the 22-calibre bullet of the ordinary revolver is calculated to do much mischief. This weighs only twenty grains, and the ordinary cartridge contains only about five grains of powder. Even if such a missile did penetrate the abdominal cavity (which is the exception) and pass through a knuckle of intestine, the opening would be so small that an eversion of the mucous membrane would be caused, sufficient to prevent the extravasation of fecal matter, while in the majority of cases the wound would be of a character such as is not followed by much hemorrhage. More commonly, however, the bullet lodges in the abdominal walls, especially if there be much adipose tissue in the latter, even when fired at very short range. If, then, he was called to such a case, and there were no symptoms present specially calling for laparotomy, he certainly would not perform this operation.

But if, on the other hand, he were called to a case in which the injury had been inflicted by what is known as an "express charge," he would expect abundant indications for its performance. In the express charge there is a 40-calibre bullet, which weighs 270 grains, and behind it there are 110 grains of powder. Even in the absence of symptoms, he would consider the case one for immediate laparotomy; for he would feel very sure that if such a missile got into the abdominal cavity at all, it would cut and tear everything that came in its way. He thought it is pretty well recognized that a blow on the abdomen from a spent ball is sometimes followed by very aggravated shock; while in other instances penetrating wounds are entirely free from shock.

In stab wounds, he would not perform laparotomy in many cases, even if he knew the wound were a penetrating one, or even if the omentum were protruding. In this connection, Dr. Wright mentioned the case of a drunken sailor, who stabbed himself in the abdomen, and, when a portion of the omentum protruded through the wound, caught hold of it, in his drunken folly, and dragged it still further out. Yet the man recovered perfectly, and that without even being laid up for an hour. On the very day that he received the injury he went to sea, and in the course of a week the protruding omentum sloughed off; after which he had no further trouble. Within the last year he had seen the same thing at Bellevue Hospital, in the case of the murderer Carpenter, who stabbed himself in the abdomen, but had no resulting symptoms. He did not believe, there-

fore, that surgical interference is called for in every case.

As to the matter of diagnosis, it is difficult to say in every case whether the peritoneum is wounded or not. In many instances there is well-marked shock simply from the force of the blow, particularly if this is in the neighborhood of the epigastrium. There are several points to be taken into consideration:

First. If the shock is extreme and protracted, the abdominal cavity has probably been penetrated.

Second. The occurrence of meteorism indicates danger to the viscera.

Third. The protrusion of the gut through the wound proves nothing as to whether the gut itself has been injured or not. This is shown, however, by the escape of the intestinal contents.

He thought, therefore, that we should be careful how we state that laparotomy is called for in any case. He then said he would go back to the consideration of the wounds made by the small pistol bullet of which he had spoken, which even when they involve a knuckle of intestine are usually of a trivial character. The penetration of the abdominal cavity by such a missile, however, is the exception, rather than the rule, and he had known one of them to be fired from a distance of only two feet and yet lodge in the belly of the pectoralis muscle. In fact, he had seen patients who had these bullets in all parts of the body, and had never known one of them to do any serious injury.

DR. ROBERT F. WEIR said that, in the main, his views were in agreement with those of Dr. Wright. He did not feel in a position to say that penetrating stab wounds of the abdomen are necessarily accompanied with injury of the intestines or abdominal viscera. Unless in any case there are symptoms indicating the presence of such complications, the surgeon has only to watch the patient carefully. In regard to gunshot wounds (a class of cases which at present is engaging the attention of the surgical mind to a large extent), there is a different state of affairs. For his own part, he had a somewhat greater respect for the capabilities of the small pistol bullet than Dr. Wright felt, since he had known it to penetrate the abdominal cavity and do a considerable amount of injury. As a rule, one of the indications is to explore the wound under any circumstances; and he thought that statistics clearly prove that every gunshot wound of the abdomen at short range should be carefully examined, in order to see whether or not it penetrates the cavity.

The question of hemorrhage always comes up in connection with the existence of shock; and it is often impossible to determine offhand, in any instance, whether the patient is suffering from the shock of the injury, or from extravasation, or from the shock of hemorrhage. If the shock is not due to hemorrhage, it will be best to wait for it to subside before performing laparotomy, as the chances of success are thereby increased. But he had learned from the experience of two sad cases that delay may prove fatal; and, therefore, he believed with Dr. Bryant that it is best to make a small exploratory incision in every case where it is impossible to decide whether the shock is due to hemorrhage or not. He would take issue with Dr. Bryant, however, in regard to his point that the simple opening shows whether there is or is not much bleeding. The blood naturally gravitates toward the lower part of the abdominal cavity, and therefore it is often necessary to pass in a sponge or a holder in order to find out the existence of hemorrhage. If this procedure did not indicate the presence of hemorrhage, he said, he would close the small wound and wait until a later time to perform actual laparotomy, in case this was called for.

Dr. Wright had stated that a small bullet might pass through the intestine without causing extravasation of feces or otherwise doing harm; but the very reasons which would make such a wound of less severity would also be the reasons why a laparotomy would be of less severity under the circumstances. For himself, he would proceed to perform laparotomy if the exploratory incision showed that the intestines were wounded; for even if there was no extravasation of feces, there would almost certainly be an escape of gas into the peritoneal cavity.

DR. ALFRED C. POST said that, personally, he has not had occasion to perform laparotomy in any of the cases under consideration. He thought, in regard to incised wounds, that it makes a very great difference in what part of the abdomen the stab is given. If in the region of the stomach and liver, there is less danger of hemorrhage than if the wound is situated in the region of the intestines. Again, if it were still lower down, it might be below the peritoneum altogether, especially if the bladder was distended at the time. In this connection he recalled a case which occurred in the city of New York at the time of the draft riots during the war. A man was stabbed, near the residence of Dr. Van Buren, in the lower part of the abdomen, and the injury was immediately followed by a free gush of urine. He was treated by Dr. Van Buren, and recovered almost without a bad symptom. In a case of this kind the safety of the patient no doubt is due to the large size of the wound, which gave free drainage and prevented the retention of urine in the tissues. A large and direct opening would also have much the same effect as regards extravasated feces. On the contrary, a small wound is liable to be followed by more serious consequences, and he had known a fecal fistula to result from the minute opening made by an aspirator needle, which, in an attempt to aspirate the bladder, had been plunged into the intestines above it. When there is fecal extravasation, he thought that laparotomy should always be performed and the abdominal cavity thoroughly cleansed. When this is done, the patient has a fair chance of recovery; but if the feces are permitted to remain in the cavity, death is inevitable.

THE CHAIRMAN remarked that the propriety of resorting to laparotomy in any case naturally depends, to a large extent, on the idea entertained by the attending surgeon as to the dangers of the operation. The question is, whether the advantages likely to result from it outweigh the dangers attending its performance. He therefore called upon Dr. Polk, who had had a large experience in laparotomy, to speak on this point.

DR. WM. M. POLK said that, so far as dangers are concerned, the results obtained, both at home and abroad, show that the exploratory incision is quite a simple affair, comparatively free from danger. It seemed to him, however, that a simple incision, such as those who confine their attention to pelvic surgery most frequently have to make, would scarcely be sufficient in

the class of cases under discussion. The gynecologist generally knows about what condition of things he expects to find, and if a large tumor is present, he sweeps his hand around it, but does not meddle much with the intestines. Even in the case of the most extensive growths, the intestines are very little disturbed; and he had noticed that whenever they were much disturbed, the danger of the operation was greatly increased. This, then, is the question. If a limited exploration is made, there is comparatively little risk; but if it is necessary to introduce the hand and feel around among the intestines, a great deal is added to the risk. Within the last two or three years, he had seen this strikingly illustrated in this city in Tait's and other similar operations. Formerly, when there were marked adhesions, the intestines were freely handled, and sometimes laid up over the abdomen, and a fatal result frequently followed. Within the last eighteen months, however, in the same class of cases, the results have been very much more favorable, and this was owing to a different mode of procedure. A much smaller incision is now used, and the adhesions are torn away by the hand without regard to hemorrhage, because the latter soon ceases, and a drainage-tube is introduced to remove the blood. Instead of the operation covering an hour or an hour and a half as before, it takes now only twenty or twenty-five minutes. The whole question of danger, therefore, it seemed to him, depends on the amount of handling of the viscera required in any given case. So far as the simple opening of the peritoneum is concerned, at the present time he regarded it as attended with as little danger as five years ago he would have regarded the sewing up of the cervix uteri.

Dr. W. Gill Wylie said that he thought the peritoneal cavity should be opened first, for the purpose of diagnosis. This whole subject, he believed, would be more clear if the etiology and pathology of shock were better understood. To his mind, the shock in these cases depends largely on changes in intra-abdominal pressure and on hemorrhage. The dangers to which Dr. Polk had alluded are due, he thought, not so much to handling of the intestines as to exposure to septic influences from the atmosphere, sponges, etc. According to his observation, the large majority of the deaths were due to septic infection. He would have no hesitation in opening the peritoneum in any case where the patient's life is in question. There is very little danger of increasing shock thereby, and he believed that when the shock is very marked, it can be inferred that there is some hemorrhage; so that the operation is urgently demanded under the circumstances. After performing operations in the abdominal cavity he not infrequently washed out the latter with a solution of bichloride of mercury, 1 : 10,000; following this with the injection of simple hot water.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, December 8, 1885.

The President, Charles McBurney, M.D., in the Chair.

SUPRAPUBIC LITHOTOMY; SUTURE OF BLADDER WOUND; PRIMARY UNION.

Dr. Pilcher presented a man, twenty-one years of age, upon whom, two weeks ago that day, he had operated for the removal of stone from the bladder by the suprapubic method, as perfected by Petersen, of Kiel. The patient had suffered from symptoms of stone about nine years. After etherization, a rubber ball having been introduced into the rectum, it was distended with about ten ounces of water, after which nine ounces of a warm solution of boracic acid were injected into the bladder through a soft rubber catheter. The result was to cause a very marked protuberance of the bladder above the pubis, and to make exposure of its anterosuperior wall, by incision above the symphysis pubis, remarkably easy. The wall of the bladder having been exposed, he followed the suggestion of von Antal, of making an oblique incision through the muscular wall, so as to increase the width of the fresh surfaces afterward to be united by suture. This step in the operation having been accomplished without serious inconvenience, the blue color of the mucous membrane of the bladder could be plainly seen by all present in the operating-room of the Post-graduate Medical School, where the operation was performed. Upon the incision into the bladder being completed, the stone was seized and removed without difficulty. It was of moderate size, weighing 207 grains in its dry state, and was composed of a nucleus of uric acid with an external layer of oxalate of lime principally, with some triple phosphates.

In this case, after removal of the stone, the ease with which the interior of the bladder could be inspected was particularly noteworthy. The posterior wall was clearly visible, and the whole anterior wall was easy of exploration.

The catheter, through which the preliminary injection of boracic acid solution had been made, was left *in situ* to insure continuous drainage of urine; the wound in the bladder was closed by seven or eight points of fine silk suture passing through only the muscular and submucous layers. The suprajacent musculotendinous layer was then closed by a running catgut suture; the subcutaneous tissue was then brought together and supported by three harelip pins, and finally a superficial line of sutures was placed through the integumental wound, a little cotton sprinkled with iodoform was laid upon the wound, and the man was put to bed. Absolute well-doing attended the after-course of the case; the catheter was removed on the ninth day, and the pins upon the day following. On the eleventh day the man went to his home, permanent primary union throughout the whole extent of the wound, without unpleasant symptoms of any kind, having taken place.

About fifteen months ago, Dr. Pilcher had advised with regard to an operation in the case of a child ten or eleven years of age, in whom, according to his wish, the suprapubic method was likewise adopted. The operation was performed by Dr. McPhail at the Brooklyn Orphan Asylum. In that case they did not attempt to close the vesical wound, and the suprapubic wound was left to granulate, while the bladder was drained by a pair of drainage tubes passing through the suprapubic wound to the base of the bladder and outwardly over the pubis and down between the thighs, after the method of Perrier. The progress of the case was as satisfactory as could be expected; granulation took place, and the wound ultimately healed, the patient being

discharged, cured, at the end of the third or fourth week.

He thought the case presented had a bearing more particularly upon what seemed to be taking place at the present time, namely, a readjustment of our views with regard to the relative merits of cutting or crushing methods for removal of stones from the bladder.

DR. BRIDDON asked Dr. Pilcher whether he objected to the operation of crushing.

DR. PILCHER replied that he would not object to crushing, yet it seemed to him that under ordinary circumstances such an operation as this is more favorable for the patient than the operation of crushing. He might say, however, he was especially led to do the suprapubic operation in this case, to illustrate to the general practitioners who formed his class, what he considered to be the best operation available to those who had not acquired the technical skill necessary to crush a stone in the bladder.

DR. SANDS thought that it would hardly be proper to allow a case of this sort, successful as it was, to go upon record without an expression of doubt as to the expediency, if not as to the propriety, of removing a stone of the size of the one presented, and which seemed to be friable, by any cutting operation. This patient had certainly recovered very promptly, else he would not have been shown within a fortnight; but it was probably within the experience of most of the surgeons present that after crushing stones quite as large as this one, and even larger, the patients had been able to leave the hospital in the course of a week. He acknowledged the very great superiority of Petersen's operation in certain cases, but he thought it could not be recommended to the general practitioner as one free from risk. It seemed to him that the operation is one which will always require considerable skill in order to avoid danger to life, and our experience is not large enough to enable us to recommend this as a preferable operation to one which has stood the test of extensive trial, and has proved to be almost absolutely safe in healthy young adults. As an example of successful operation, he would accept Dr. Pilcher's case, but as an example for imitation he would reject it.

DR. A. C. POST recalled a case in which he performed lithotripsy long before evacuation of the bladder had been introduced, three crushing operations having been performed at his clinic, the patient returning to his home on each occasion, a distance of nineteen miles. No unpleasant symptoms developed.

DR. C. K. BRIDDON said that within a few weeks past he removed a stone by the crushing operation in a man more than seventy years of age who had enlargement of the prostate and cystitis of an aggravated character. The operation lasted three hours, and more than six hundred grains of calculous material were removed, yet the man was able to leave the hospital within a week. Eight or nine days ago he performed Bigelow's operation on a man sixty-nine years of age, who left the hospital within a week, with relief from his bladder symptoms. But he thought there was sufficient justification for the operation performed by Dr. Pilcher, for he certainly would prefer to be cut for a stone than to have the stone crushed by a man who was not accustomed to do the crushing operation.

THE PRESIDENT asked Dr. Briddon whether he would not consider the first case to which he had referred as specially suited for the high operation.

DR. BRIDDON replied that he would not want any better result than that obtained by crushing.

THE PRESIDENT said that would apply to Dr. Pilcher's case as well, which was altogether of a different character.

DR. BRIDDON said that if he should have cut this man he would have chosen the high operation in preference to the low one. In such a case the high operation is certainly preferable.

DR. POST asked whether there are not two sides to that question. In a case of enlarged prostate with cystitis, does not the low operation afford a fair prospect of relief of the prostatic and vesical difficulty independently of removal of the stone? A number of cases had been placed on record with such a result by high authorities, such as Sir Wm. Ferguson, Reginald Harrison, Dr. Gouley, and others.

DR. BRIDDON said that such had not been his experience. If relief followed the operation, it was only of short duration, the symptoms returning with as much severity as before.

DR. T. M. MARKOE remarked that, after all, there remain a certain number of cases, small to be sure, in which Bigelow's operation is unsuitable by reason of the largeness or hardness of the stone, and in which he thought the question as to the advisability of the high operation in preference to the low one fairly presented itself. As to a comparison of the high or low operation with crushing, general surgical experience is decidedly in favor of the crushing operation. But in cases in which crushing is inadvisable, the high operation, as modified by Petersen, he regards as, in certain cases, preferable to any other, and it must be accepted as an admirable contribution to modern surgery.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, December 16, 1885.

THE PRESIDENT, R. J. LEVIS, M.D., IN THE CHAIR.

DR. WM. M. WELCH read a paper entitled

CLINICAL NOTE ON THE USE OF ANTIPYRIN.

(See page 9.)

DR. J. S. NEFF said that he had used it about forty times in typhoid fever. The drug is only used to reduce very high temperatures and that result is obtained in the vast number of cases. When given in large doses to animals it produces death by cardiac paralysis. If given properly, antipyrin rarely produces nausea. If given simply in solution in water, it produces nausea in about two or three cases out of every ten. If administered in a simple bitter or aromatic, the proportion is not more than one in ten. He had never seen the delirium increased or headache produced by it. In typhoid fever he had seen large doses fail to reduce temperature, and in some cases where the temperature was reduced, there was no amelioration of the other symptoms, and in the course of two or three hours the temperature again rose; in such cases it is well to suspend its administration. He relied upon quinine in ordinary cases. Profuse sweating is very constant after

the use of antipyrin. If the temperature rises to 103° and sponging does not control it, then he uses antipyrin.

DR. L. K. BALDWIN, having seen the case reported, fully corroborated what had been said by Dr. Welch. The patient's condition after the administration of the antipyrin was alarming, and he felt sure that if the dose had been fifteen or twenty grains, the result would have been fatal in two or three hours. He was under the impression that the drug is apt to be used recklessly, as reports on its use give such a wide margin in dose—that is, from ten to sixty grains or more in a few hours.

DR. NEFF claimed that antipyrin is useful in the symptomatic treatment of typhoid fever for the reduction of temperature. It has also been used in sunstroke, puerperal septicæmia, and other affections. It is more particularly in the early periods of typhoid that it is especially useful in reducing the temperature. The fever of the latter periods is of the same nature as surgical fever, and is due to the absorption of putrefactive matters from the ulcerated Peyer's patches. In such cases, of course, it is necessary to get rid of the cause in order permanently to lower the temperature. The drug must be used judiciously, and where a person is in collapse it should be used with great caution. He had never seen it produce collapse or even a chill. Where the temperature is over 104°, he usually gives twenty grains. If at the end of one hour the temperature be not reduced, ten grains more are administered, to be followed in one hour, if necessary, by another twenty grain dose. It has been claimed that antipyrin also reduces the pulse. This is not always so. The pulse falls, but not in the same ratio as the temperature, and at times the pulse is not reduced at all. He would not regard Dr. Welch's case as a death from antipyrin. From eighty to one hundred grains per diem have been given at the Philadelphia and Pennsylvania Hospitals without any alarming symptoms being produced.

DR. A. W. MACCOY said that his experience led him to believe that the remedy is beneficial in much smaller doses than those ordinarily recommended. He uses from five to ten grains, and has not exceeded ten grain doses in tuberculosis. He has found it useful in the high temperature and night-sweats of phthisis.

DR. WELCH was inclined to believe, from what he had read in the journals and from the discussion elicited, that his experience in this case was exceptional. He had not reported it as a case of death from antipyrin, as the patient lived five days after the administration of the dose, and reacted fully from its depressing effect.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

Thirteenth Annual Meeting, held at Washington, D. C., December 8, 9, 10, and 11, 1885.

(Specially reported for THE MEDICAL NEWS.)

THURSDAY, DECEMBER 10TH.—THIRD DAY.

MORNING SESSION.

THE Association received, and referred to a special committee for consideration and recommendation, a series of resolutions from the Board of Health of Philadelphia, in which it is resolved that no rags from foreign ports shall be permitted to land at the port of Philadelphia until after they have been disinfected. The necessity for passing judgment upon the matter of the importation of rags was urged. The resolutions were referred to a special committee for consideration.

The Executive Committee presented a modification of the resolution of Dr. Lamb, providing for the appointment of a committee to examine into

THE SANITARY CONDITIONS OF THE SEVERAL TRADES,

and suggest improvements therein. It was adopted.

DR. JOHN H. RAUCH, of Illinois, then read the first paper of the day, entitled,

MARITIME QUARANTINES FROM THE MOUTH OF THE ST. LAWRENCE TO THE RIO GRANDE,

which was a report upon the quarantine systems of each of the coast States. He described the various improvements which had been made in quarantine matters at the different ports visited, and a separate report for each State.

DR. JOSEPH HOLT, of New Orleans, then spoke of the sanitary measures taken for the protection of New Orleans, both municipal and maritime. He described the measures not yet taken by New Orleans for municipal sanitation, but toward which the people are being educated by health boards and the intelligent press. Already a plan is bein prepared for the systematic sewerage of the city. Maritime sanitation has taken the place of quarantine along the coast. The theory of germ origin for the essential cause of diphtheria, consumption, smallpox, yellow fever, and kindred diseases, has passed from the realm of uncertainty into a crystallized fact. Burning tar barrels, prayers, and processions, are no longer relied upon as disinfectants. We have tried these, and they have invariably failed. We are no longer fighting the devil and his works, but a microscopic germ—a little leaven, which, if not speedily destroyed, leavens the whole lump. Yellow fever and cholera are due to living organisms, and it is to the destruction of these that our efforts must be directed. The surest prevention of a conflagration is to quench the first spark. The surest prevention of an epidemic is to act on the first suspicion of an epidemic disease.

He spoke of the experiments in Brazil and Mexico, relative to inoculation for yellow fever, and stated that it has been fully proved that the germ can be inoculated into the body of an unvaccinated person, and that a mild form of yellow fever will be thereby produced, and that persons so inoculated have been able to pass unscathed through the most virulent epidemics of that disease. The principal object of his visit to Washington was to present the following resolutions to the Association, with the request that they would bring them to the attention of Congress:

Whereas, The question of immunity from yellow fever is so intimately connected with the social, industrial, and commercial growth of Tennessee, and the Southern Atlantic and the Gulf States of the Union, as to determine the destiny of Memphis, Charleston, Savannah, Pensacola, Mobile, New Orleans, and Galveston; and,

Whereas, A large accumulating mass of testimony that the power of protecting the unacclimated against yellow fever has been discovered and proved in the inoculations of the essential germ or cause of the disease by methods distinctly formulated and available,

these aforesaid declarations and numerous instances cited in corroboration, emanating from medical scientists at the head of the biological departments in the highest institutions of learning in Mexico and Brazil, authorized by and bearing the endorsement of their respective governments:

Resolved, That we, the representatives of the boards of health in the several States of the Union, and we, the officers and members of the American Public Health Association, regarding the question as preeminently a vital issue, as one, in its assumptions, true or false, and, if true, of incalculable worth, surpassing the computation of many millions of dollars, and to the saving of tens of thousands of lives of its own people, hereby petition and urge upon both branches of Congress, now assembled, to appoint a commission for the purpose of making a complete investigation of, and reporting after a thorough examination of the methods pursued, their effectiveness in protecting the unacclimated against the yellow fever infection, together with all associated observations and experiments that may be ascertained.

Resolved, That in the aforesaid petition the commission shall be stated to consist of three persons, one of whom shall be of known ability and special attainment in biological research, particularly in the department of microscopic investigation and culture of the essential germ as causative of the infectious and contagious diseases. The other two members of the commission shall be medical men of recognized ability, based upon long and ample experience, competent to give expert consideration to all phases of the symptoms and course of yellow fever in any form wherein the phenomena of the disease may be present, whether induced in the course of pestilential invasion or in purposely devised inoculation.

Resolved, That this commission aforesaid shall proceed, at the earliest possible moment, to Rio de Janeiro as the first field of its labors. Having completed there its work, it shall proceed to Mexico, and, if necessary in the accumulation of testimony, to Panama, Colon, and Havana.

Resolved, That the sum of $30,000, or so much thereof as may be actually required, be appropriated to pay the necessary and unavoidable travelling and other expenses and the salaries of the members of the commission.

Resolved, That the sum of $5000 shall be paid as a recompense to each member of the aforesaid commission.

The last paper of the morning session, by DR. S. T. ARMSTRONG, U. S. Marine Service, was entitled

MARITIME SANITATION,

and treated of the subject from the standpoint of the sailor, the passenger, the cargo, the vessel, and the port. He called attention to the necessity of legislation for the preliminary examination of sailors before shipment, and of a required minimum cubic space in the sleeping quarters of the crew, etc., by medical officers of the Treasury Department, instead of collectors of customs. Disinfection of cargoes and vessels from infected ports, both by shipmasters and by inspecting officers at the port of arrival. The sanitary condition of the port was only alluded to, as he considered this to be the province of the Association.

DR. RAYMOND, of Brooklyn, offered a resolution that the subject of

THE PRACTICABILITY OF DISINFECTING SEWERS

be referred to the Committee on Disinfectants, with a request to report at the next meeting. The resolution was referred to the Executive Committee.

The Association then adjourned to call at the Executive Mansion and

PAY THEIR RESPECTS TO THE PRESIDENT,

who received them in the East Room, and greeted them cordially, shaking hands with about four hundred members.

THE EXECUTIVE COMMITTEE

held a session immediately after the adjournment of the morning session, and it was decided that the *next annual meeting* of the Association should be held at Toronto, Ontario. Memphis, Tenn., was very urgently recommended.

THE AWARD OF THE LOMB PRIZES

for the best essays was next in order.

For the best essay on *Healthy Homes and Foods for the Working Classes*, the second prize was awarded to Victor C. Vaughn, of Ann Arbor, Mich. The first prize was not awarded.

For the best essay on *The Sanitary Condition and Necessities of School Houses and School Life*, the second prize was awarded to Dr. F. Lincoln, of Boston, Mass. The first prize was not awarded.

For the best essay on *Disinfection and Individual Prophylaxis against Infectious Diseases*, the first prize was awarded to Dr. George W. Sternberg, of Baltimore, Md., amid great applause.

For the next paper, *The Preventable Causes of Diseases, Injury, and Death in American Manufactories and Workshops, and the best means and appliances for preventing and avoiding them*, the second prize was awarded to Dr. George H. Ireland, of Springfield, Mass. The first prize was not awarded.

The President then introduced Mr. Henry Lomb, who, upon motion of Dr. J. S. Billings, was unanimously elected a life member of the Association, amid great applause.

PROF. D. A. SARGENT, of Harvard University, then submitted

THE REPORT OF THE COMMITTEE ON SCHOOL HYGIENE,

which set forth that the uneven manner in which physical and mental training is distributed is shown at once by the fact that those schools which have large playgrounds attached, and a river upon which to row boats, never fail to advertise the fact, while those which do not possess these advantages give their attention to theoretical training. As a consequence, there are unsatisfactory reports from all sides. Here we have all muscle and no brain development, and there superior mental attainments and nervous prostration. The Committee thought that course of training should be adopted which actual observation had demonstrated to distribute most thoroughly physical exercise in proper proportion with the mental exercises of education. Youths

should also be thoroughly taught the first laws of the body, the necessity of cleanliness, pure air in houses, etc., and not only taught these principles, but shown how to make practical use of their knowledge.

Dr. John Morris, of Baltimore, then read

THE REPORT OF THE COMMITTEE ON THE DISPOSAL OF THE DEAD.

In this country six cremation societies have been established, and two crematories, with indications of an increase. If the present mode of burial is continued, great and radical reforms must be instituted to protect the living from the contamination of the dead. Interment must be regulated by legislation, and placed under the control of the health authorities. Not only the time, but all the details of burial must be regulated by ordinance. Embalming should be absolutely prohibited; dissolution of the body should be hastened, not retarded. No doubt the general acceptance of the germ theory, and the surprising discoveries of Pasteur and others concerning the life and office of groundworms, have materially influenced public thought in this matter. Even those who do not favor cremation admit the necessity of reform in the present mode of burial. Cremation is gaining ground in Europe. A bill legalizing the process has been introduced in the French Chamber of Deputies, and is supported by such advanced thinkers as Paul Bert and Renan. It is proposed to build a large crematorium near Paris, and an engineer has been sent to Italy to study the best plan. Three hundred and ninety-six bodies were cremated in Italy last year. A valuable contribution to the subject of inhumation has been recently made in France by Drs. Dumesnil and Fauvel. The deductions therefrom are that in every cavity dug where organic matters are decomposing, there are produced two phenomena which jeopardize the lives of those exposed to their influence, viz., the great and rapid disengagement of carbonic acid, and notable diminution of oxygen in the air.

The Spanish Cortes has passed a bill allowing cremation. The dreadful scenes in Granada, where hundreds of bodies lay for days uncovered during the late cholera epidemic, no doubt influenced the legislation. Germany is also adopting cremation, and the *Berlin Verein für innere Medicin* has declared that the best authorities in the field of hygiene have clearly proved that cremation is the safest preventative against the spread of contagious diseases by corpses. There were one hundred and eighty-six cremations in Germany last year.

In Denmark the subject is exciting marked attention. At the meeting of the International Medical Congress, held at Copenhagen in 1884, Dr. Leuson presented a report on the cemeteries of Denmark, and their influence on the public health. After a most thorough and scientific investigation into the public health of Copenhagen, he concludes that it has been repeatedly demonstrated that pestilential diseases have been traced to the use of water from streams or wells contaminated by the presence of cadaveric decomposition. Other schemes for the disposal of the dead have been urged, among them the encasement of the body in a sort of papier-maché coffin, which is soluble and permits the surrounding earth to reach the corpse in a very short time.

In conclusion, Dr. Morris said:

"If incineration were accepted, all these evils would be arrested. It is generally admitted that this process should be adopted in all great epidemics and after battles, but it would be wise to extend it to cases of zymotic disease, such as cholera, smallpox, scarlet fever, and diphtheria. These poisons are preserved for years, and at certain times and under certain conditions vent their destructive force on the human race."

Considerable discussion followed the reading of this paper, a majority of the speakers apparently favoring cremation.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 17, 1885.

The President, A. Jacobi, M.D., in the Chair.

Dr. T. Gaillard Thomas read a paper on

VAGINAL AND VULVAR ENTEROCELE.

He commenced with the statement that there are five varieties of hernia which may show themselves by the vagina and vulva, viz., (1) cystocele, (2) rectocele, (3) vaginal enterocele, (4) pudendal enterocele, (5) perineal enterocele. In the latter there is a descent of the small intestines by protrusion through the perineum. Other varieties might also be given, based on the contents of these hernial sacs, in which the ovaries, the uterus, and the Fallopian tubes, either empty or filled with the products of conception, have in exceptional cases been found; or upon some extremely rare development of this condition, such as in one case of Burns, in which the base of the bladder, passing down alongside of the right wall of the vagina, formed a hernia in the labium majus of that side. But for practical purposes it is only necessary to consider the varieties of hernia named, and this paper was confined to descent of the intestines through the pelvic roof, and their protrusion into the labia majora, the vagina, or through the perineum.

It is curious to see how very generally these varieties of hernia have been ignored in systematic treatises on gynecology, and this is the more remarkable, since errors in diagnosis of them are very liable to occur. Even in literature outside of systematic treatises it is difficult to find much upon the subject. Garengrot, in 1736, according to A. Bérard, was the first to describe this form of hernia, and he was followed by Verdier, Haen, Sandifort, and Richter. Sir Astley Cooper treated of it fully in his celebrated work upon hernia, in 1804. Bérard's *Dictionnaire de Médecine*, published in 1846, gave the best account of it which Dr. Thomas had met.

Having mentioned various instances of this accident which have been put on record by different writers, he went on to speak particularly of

Vaginal enterocele, which consists in a descent of the intestines into the pelvic cavity, either in front of or posterior to the broad ligament of one side. As Boyer and Richter long since pointed out, the intestines never descend directly in the median line, either anteriorly or posteriorly, on account of the intimate relations of the vagina at these points; but always descend a little obliquely, and most generally posteriorly. Usually, it is the intestine alone that descends in these hernial protrusions, but sometimes the omentum accompanies it; and usually, also, it is the small intestine that composes the hernia, but the large intestine may also be involved.

Vaginal hernia, as a rule, develops itself in the fol-

lowing manner: A loop of intestine gradually pushes downward the prolongation of the peritoneum which forms the pouch of Douglas, until it impinges upon the outside of the wall of the vagina, and causes it to arch inward. This mechanical influence being continued, and gradually increased, a tumor forms in the vaginal canal, invests one wall of that canal more and more completely, and may end by escaping from the vulva and hanging outside the body as a complete prolapse of the bladder, or of the uterus, would do.

Under these circumstances, it is evident that the tumor which protrudes has for its component parts, first, the invested vaginal wall; second, the peritoneum; and, third, the intestines. As Bérard has pointed out, it is very important to determine whether the entire thickness of the vaginal wall is inverted and forms the envelope of the tumor, or whether the external coat is torn so as to present an opening through which the hernia passes; and although in the literature of the subject reports of several autopsies are to be found, the point apparently still remains unsettled.

Unquestionably the greatest danger attending this form of hernia, as well as the two other varieties that are to be considered, arises from the possibility of an error of diagnosis on the part of the impulsive or unwary surgeon. If the tumor occurs during labor and obstructs the progress of the fœtal head, it may, perhaps, be mistaken for an ovarian or parovarian cyst with a long pedicle, which has been pushed into the pelvis, in which case a trocar and canula may be plunged in and the operator be horrified at the escape of fecal matter and intestinal gases. Or, if the condition is found to exist in the non-parturient woman, an effort may be made to remove it, which will open the eyes of the operator in a very painful manner in regard to the true nature of the tumor. In this connection Dr. Thomas quoted two instructive cases—one published in the *Centralblatt für Chirurgie* for May, 1879, and one related by Gunz.

Parturition is the most frequent cause of the varieties of hernia under consideration, but it is not to be lost sight of that some of the most striking cases of the accident recorded have occurred in multiparous women. These are usually due to violent efforts, falls, and the previous existence of pelvic tumors which have burst or been removed. Vaginal hernia, so long as it remains in the pelvic cavity and does not interfere with parturition, is usually a matter of little moment and the source of little inconvenience. Under certain malign influences, however, occurring during parturition, as well as in the non-parturient state, such as pressure from the fœtal head, inflammatory processes, fecal impaction, torsion of the contents of the sac, or the existence of a neoplasm, strangulation may occur.

The symptoms which are then apt to develop are: difficulty in locomotion, pelvic tenesmus, colicky pains, dragging sensations, tendency to constipation, and, in time, vomiting. Should the accident complicate parturition, obstructed labor is apt to result. Upon vaginal examination a tumor of greater or less size is found in the vagina, and is diagnosticated by the following physical signs: It is supple, soft, and yielding; decreases upon pressure; gives a sense of gurgling to the finger, if not to the ear; increases upon the patient's coughing or straining; yields resonance upon percussion; and is very generally reducible if the patient be placed in the knee-chest position, and efficient taxis is practised.

Vaginal enterocele may be confounded by a careless and rapid diagnostician with the following conditions: prolapse of vagina, uterus, bladder, or rectum, or with a combination of these displacements; with vaginal cyst; with parovarian or ovarian cyst; with a fibrous tumor presenting low down in the pelvis, with a "cold abscess" of the pelvis; or with a marked case of tubal dropsy. Error is likely to creep in from the practitioner's being too confident, too much off his guard, and too little inclined to consider the possibility of a mistake. If he approaches these cases calmly, philosophically, and in a proper spirit of diagnostic investigation, it is very improbable that an erroneous diagnosis will occur. Having mentioned that most cases present striking features, he quoted the graphic description of a case given by Sir Astley Cooper.

It is to be remembered that, like hernia occurring elsewhere, these forms now under consideration may show themselves in two ways; first, by a brusque and sudden development, marked by alarming and decided symptoms; and, secondly, by a development so gradual and uneventful as to symptoms as to escape recognition entirely until the mere mechanical results of the hernial tumor force themselves upon the attention of patient or physician. In certain very rare cases acute vaginal hernia occurs as a consequence of some traumatic influence destroying the continuity of this canal in its upper part, and a striking instance of this which occurred in the service of M. Auger, was reported by M. Pennel in *La France Médicale* for November, 1881. Dr. Thomas also related two cases which had occurred under his own observation. There is more danger of erroneous diagnosis in the gradually developing, creeping, insidious cases than in the acute ones.

Pudendal enterocele demonstrates its existence by the presence of an elastic tumor, about as large as a small hen's egg, or a pigeon's egg, about the middle of the labium majus of one side. Having explained its mode of origin, he said that some of the French writers divide this form of hernia into two varieties: first, anterior labial hernia; and, second, posterior labial hernia. From inguinal hernia reaching by descent into the labium majus the internal variety may be thus distinguished: 1st. The finger, pushing the tumor upward, will pass into the pelvic cavity between the ischium and vagina. 2d. At the level of the os uteri, or thereabout, it will enter the pelvic roof. 3d. Pressure being maintained in the inguinal canal, and the patient being ordered to cough, it will, in spite of the pressure, recur.

The following conditions were mentioned as liable to be confounded with pudendal hernia: cyst or abscess of the vulvo-vaginal gland; abscess of labium majus; fatty or fibrous tumors of the labium; tumors descending from the pelvic cavity. Cases in illustration of some of these points were quoted, and Dr. Thomas then said that the differentiation of pudendal hernia from these conditions of the labia should be very carefully considered; for if an erroneous diagnosis were made here, a fatal issue might result. The diagnostic signs which prove most reliable, and which may almost be styled pathognomonic, are these: (1) Airy feeling upon palpation; (2) gurgling upon replacement; (3) diminished tension in the dorsal decubitus; (4) diminution of bulk upon

taxis; (5) resonance upon percussion; (6) percussion upon coughing; (7) intestinal pains of colicky character.

Perineal hernia may affect both male and female, and in the latter it consists of the descent of the intestine between the vagina and rectum, the advance being made posterior to the broad ligament, and continuing until the perineal muscles are forced apart, and the gut, with its perineal envelope, is arrested by the skin. All these varieties of hernia are usually readily amenable to taxis, and this Dr. Thomas had invariably found to be greatly facilitated by the knee-chest or genu-pectoral position. In some rare cases strangulation occurred. Under these circumstances the same surgical practice is indicated as in inguinal or crural hernia, viz., cautious opening of the sac and section of the constricting band, by passing up a probe-pointed bistoury.

Before closing this paper he said he desired to put on record a remarkable case of extreme vaginal hernia, which presented some features which he had never met with in such literature of the subject as had fallen under his observation. The patient was a married lady and a multipara, thirty-nine years of age, who came from a country town to consult him during the past autumn. The history that she gave was, that six years ago she discovered a lump in the vulva, in consequence of which she suffered from difficulty of locomotion, difficult defecation and urination, pain, and other distressing symptoms. This lump gradually increased in size till, hanging outside the body, it reached to the middle of the thigh on the right side. In the meanwhile all the previous symptoms became intensely aggravated, and the patient was now greatly emaciated. While the tumor hung down upon the thigh she could neither stand nor walk without extreme suffering; and when it was pushed up into the pelvis its presence gave rise to so much pain and discomfort that she was compelled to force it out again. She had consulted a large number of physicians without obtaining relief, and both she and her husband were now desperate, being willing to try any expedient whatever that promised any hope.

On inspection, the tumor was found to present all the gross appearances of an enormous cystocele; but a closer examination showed that it was of an entirely different nature. It was found to be firmly attached to the ischium on the right side; while the uterus was pressed almost out of reach on the left side of the pelvis. On inserting a catheter into the bladder, the latter was ascertained to be high up, extending obliquely in front of the uterus, and to have no connection whatever with the tumor. By taxis the tumor could be replaced within the pelvis, and in this reposition an extremely slight gurgling sound (which occurred only once) was elicited. There could be no doubt, however, that it was a case of hernia.

This was a case in which all the simpler methods of treatment had failed to afford any relief, and as the weight of the mass, and the pressure exerted by it on the bladder and rectum, were so great as to render the woman utterly miserable, Dr. Thomas proposed the following operation: Perform laparotomy, an assistant meanwhile pushing the tumor well within the pelvis; drag it up into the abdomen, and, all the arteries having been drawn out of the sac, fasten it by sutures in the abdominal wound, the heavy tumor being sustained by two knitting needles crossed. As soon as the operation was explained, the proposal was gladly accepted by the lady and her husband, and in the early part of November last, in the presence of his colleagues, Drs. Emmet and Bozeman, of the Woman's Hospital, who entirely approved of the procedure, laparotomy was performed.

On cutting through the abdominal walls he was surprised to encounter what appeared to be a soft fibrous tumor, on a level with the symphysis pubis, which was covered by peritoneum, and very movable. It had no connection with either the uterus or the bladder. He decided at once to remove it, and this was done, after denuding it of its peritoneal covering. Drainage was then secured by means of a glass tube, and the patient made a good recovery. It is now five weeks after the operation, and there has been no return as yet of the pain or other troublesome symptoms; but he could not but feel somewhat apprehensive about the future. It seemed to him that the growth removed had been the original cause of the vaginal hernia.

In regard to the nature of the tumor, Dr. Thomas read the report made to him by Dr. H. C. Coe, pathologist to the Woman's Hospital. It was a soft, shapeless mass, $8\frac{1}{2}$ by $5\frac{3}{4}$ inches long, and $\frac{3}{8}$ to $\frac{1}{2}$ inch thick, the surface of which had a good vascular supply. On section, there was no sign of a cyst formation. After describing its microscopical structure, of which fibro-muscular tissue formed a conspicuous element, Dr. Coe gave the following inferences: (1) It is not an organ, such as the bladder, for instance. (2) It is not an ovarian cyst. (3) It is not inflammatory tissue. He then stated that two theories had occurred to him as possibly accounting for the conditions found. The first was, that the tumor was an unusual growth of the pelvic connective tissue; and the second, that it was a softened uterine fibroid. The former supposition seemed to him the more likely to be correct.

Having finished the pathologist's report, Dr. Thomas referred to several cases of connective tissue growths, such as tumors of the broad ligaments, which had been reported by A. Martin, Schröder, and Hofmeier, the notes of which had been kindly collected for him by Dr. M'Cosh. In conclusion, he said:

Unfortunately, little can be said concerning the treatment of vaginal or vulvar hernia, for the reason that there is but one variety, the pudendal, which eventuates from inguinal hernia, for which very much can be done. That variety is amenable to treatment by the ordinary truss, as inguinal hernia is. The other varieties can, to a limited degree, be relieved by pessaries, hernial pads, abdominal bandages, etc.; but we are poor in methods of decided relief, and utterly wanting in those of cure. It appears to me that the plan suggested and partially carried out in the case which I have related, promises more than any other which has as yet been brought forward; but of the validity of this surmise, time and experience must give the proof. Certain I am, that if another case of large vaginal hernia presented itself, I should feel inclined to try laparotomy; dragging up the sac, and fastening it in the abdominal wound. B. Schmidt says, in Billroth and Pitha's *Handbuch*, that attempts were made by Huguier at radical cure of vaginal hernia, by an oval excision of part of the posterior vaginal wall and closure by suture, but without any lasting result. He must, indeed, be a sanguine surgeon who hopes for much from such procedures.

DR. F. A. CASTLE said that he had sometimes been struck with the curious contents of these hernial tumors. Thus, he had seen reported in the journals a case in which a portion of a catarrhal and dilated stomach was found in the sac.

CORRESPONDENCE.

RESECTION OF THE JAW FOR ANCHYLOSIS.

To the Editor of THE MEDICAL NEWS.

SIR: In your recent review of the operation of excision of the condyle for anchylosis of the jaw, in the issue of November 21st, p. 573, you credit American surgery with three of the thirteen cases of which you find record. May I beg leave to call to your attention a case of my own in which a brilliant result was obtained. It was done December 10, 1879, and reported in full in the *New York Med. Journal* for April, 1880. I have seen the patient recently, five years after the operation, and the action of the jaw is absolutely *perfect*.

The only other case I know of, which also was omitted from your list, was done by the late Dr. James L. Little in 1873—and resulted equally well.

The entire neck of the condyle was excised in both cases, though by different incisions.

Very truly, your obedient servant,

ROBERT ABBE, M.D.

32 EAST TWENTIETH ST., N. Y.

NEWS ITEMS.

MONTREAL.

(*From our Special Correspondent.*)

SMALLPOX.—The epidemic is almost at an end. During the last week the number of deaths from smallpox has been daily diminishing in the city proper. There have been very few new cases reported, and on some days no deaths at all. The suburbs are still suffering from the epidemic, and, not being under the jurisdiction of the city, decline to isolate cases or enforce vaccination. They have yet a daily mortality of from five to ten. The Board of Health have at last commenced to prosecute citizens refusing to be vaccinated. Several convictions have already been secured, and fines of twenty dollars have been imposed.

LONGUE POINTE ASYLUM.—This now notorious institution is again before the public as one of the few representatives of mediævalism. The conventual authorities not only believe they have special gifts fitting them for the treatment of the insane, but that their heavenly mission also extends to matters of hygiene and public health. It appears that, on the breaking out of the smallpox epidemic, some five months ago, orders were given by the Central Board of Health to have all the members of the Longue Pointe Asylum vaccinated. No notice was taken of this order. The government then directed Dr. Henry Howard, their visiting physician, to see that vaccination was thoroughly carried out. He went to the Asylum with his two assistants, but was refused admission by the Lady Superior, who told him that their own physicians were, under her direction, vaccinating the inmates. Nothing more was done. A few days ago a report spread abroad that smallpox had broken out in the Asylum. This proved, on investigation, to be true; and quite a number of patients are suffering from the disease. There have already been several deaths; but, as the Asylum authorities refuse to give any information to the Board of Health, the number of cases and number of deaths are not known.

Dr. Howard visited the Asylum again last week with his assistants, for the purpose of vaccinating, but was again refused admission, but he insisted on examining the patients, and out of 274 examined he found that only 128 had been vaccinated. The Lady Superior said that many were not in a condition of health proper for vaccination.

The Lady Superior, in a letter to one of the papers, stated that as many as 600 of the 1200 inmates had been vaccinated, and that vaccination had been going on for several months past, and was still going on. The number of successful vaccinations was not stated. If it takes five months to vaccinate 600, how long will it take to vaccinate 1200? is a problem which it is not very difficult to solve. In the meantime the fact remains, that smallpox has broken out in the institution, and several deaths have occurred.

It is stated that the Board of Health intend to institute immediately legal proceedings against the Nuns of the Providence of St. Jean de Dieu in general, and the Lady Superior, Sister Theresa de Jesus, in particular. It remains to be seen whether a Society, which defies, not only the Devil and all his works, but the government and the Board of Health, will have the temerity to defy also the majesty of the law.

A LARYNGOLOGICAL SECTION OF THE NEW YORK ACADEMY OF MEDICINE.—A meeting called for the organization of this Section was held in the rooms of the Academy on the evening of December 23, 1885, the President of the Academy occupying the Chair. A valuable paper, entitled "The Surgical Uses of Electricity in the Upper Air-passages," was read by Dr. R. P. Lincoln, and was followed by an interesting discussion.

Dr. Rufus P. Lincoln was elected President, and Dr. S. Bryson Delavan Secretary of the Section for the ensuing year, and a general plan of organization adopted. The interest in the Section manifested by the members present gave gratifying assurance as to its future success.

THE PROPOSED INTERNATIONAL MEDICAL CONGRESS.—A press dispatch from Washington, dated December 29th, states that a physician of that city, now in Paris, writes to a friend deprecating the lack of harmony among members of the American Medical Association, and says that the controversies prevailing among the medical profession here are likely to make the international convention, which it is proposed to hold in Washington in 1887, a failure. The writer says: "The continued agitation and factional fight among the members of the American Medical Association are producing the most unfortunate results among the physicians and surgeons of Paris. Many have already concluded that the meeting of the International Medical Congress at Washington will not be largely attended, and consequently not a success, and have therefore determined not to make the long journey to America. It will re-

quire the greatest harmony of action, and often repeated assurances that no further difficulties remain to hamper or prevent the convening of the Medical Congress in 1887, to remove the bad impressions and opinions already formed."

A French View of the International Congress.—The following paragraphs conclude a lengthy editorial in *Le Progrès Médical*, of Dec. 12th, on the Congress embroglio:

"What will be the result of this quarrel? Is it of a nature to compromise seriously the success of the Congress? If the sharpshooting which we have already described continues, it is very evident that the European physicians will hesitate considerably before crossing the Atlantic to accept the hospitality of a medical body so profoundly divided. It would be very desirable, from every point of view, that harmony of some sort should be established among our brethren of the United States. There are at stake the good fame of American physicians and the future of the medical relations between Europe and America. Indeed, the Congress of 1887 is called largely for the purpose of increasing these relations, and this to the mutual benefit of both continents.

"Passing over the material, economic side of the question, who can deny the civilizing effects of international medical congresses? They are to science what the international expositions are to commerce and the industries of nations. They multiply scientific relations, they make closer the bonds which unite *savants* of all countries, they aid in the diffusion of ideas and of discoveries; they do not simply mark steps of progress, they actually aid progress itself. It is for all these general reasons that we make an appeal for union and accord. It would be most grievous to record the abortion of the Congress at Washington, for the great American nation has all that is needed to give to this Congress a success and brilliancy equal, if not superior, to those of the older nations."

Prizes of the French Temperance Society.—For the year 1886 no especial subject is obligatory, the requirement being that the essay presented shall bear upon some aspect of the subject of temperance in the use of alcohol. The essay is not rendered ineligible by having been previously published.

For the year 1887 the Society requires the presentation of a brochure to be called "The Mothers' Book: a manual for the use of women who desire to preserve their families from alcoholism." The prize offered is 1000 francs.

M. Pasteur's Hydrophobia Patients.—On Sunday, November 29th, a mad dog ran about the streets of a French village, and bit six people, including a police-sergeant. The preliminary precautions were taken, and the six patients were conveyed to M. Pasteur's laboratory. There are sixty-two people now under M. Pasteur's treatment; they have travelled from all parts of the world after reading his communication to the Académie des Sciences. We are authorized to state that M. Pasteur will receive for treatment any one who has been bitten by a mad dog, and is in danger of being seized by hydrophobia.

M. Gomot, the Minister of Agriculture, has officially visited the laboratory of M. Pasteur. He is so well satisfied with his visit that, it is announced, he will ask the Chambers to enable him to practise inoculation against rabies on a large scale, and to treat human beings suffering from that malady in a special hospital. About forty persons were under treatment when M. Gomot was at M. Pasteur's.—*British Med. Journal*, Dec. 12 and 19, 1885.

A New Position.—A young woman who recently received a medical degree in Paris, has been appointed medical examiner of girls in the Parisian municipal schools. Her duties are to see that the girls are not overworked, and that they accomplish their tasks under good sanitary conditions.

Middlemore Ophthalmic Prize.—The Middlemore ophthalmic prize of £50, offered by the British Medical Association, is again announced: "For the best essay on the scientific and practical value of improvements in ophthalmological medicine or surgery, made or published during the last three years."

NOTES AND QUERIES.

DR. ALBERT H. SMITH.

At the last meeting of the Philadelphia Clinical Society the following resolution was unanimously adopted:

In view of the recent death of Dr. Albert H. Smith, a valued member of this Society, it is proper that we place on record our high estimate of his character and worth. Few men were more relied upon in our professional or personal relations. He was ever a counsellor upon whose judgment and support we relied; and his uprightness and learning lent weight to his opinions and advice.

Though precluded by sickness from an active participation in our later proceedings, yet his earnest sympathy with our objects was well known to us and highly prized.

His professional attainments will ever be both an example and a stimulus to us.

To his family we extend our tenderest and deepest sympathy.

Resolved, That this minute be entered upon our minutes, and a copy be sent to his family, and be published in The Medical News.

Ida E Richardson,
Corresponding Secretary.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM DECEMBER 22 TO DECEMBER 28, 1885.

Fryer, B. E., *Major and Surgeon*.—Sick leave extended six months on Surgeon's certificate of disability.—*S. O.* 292, *A. G. O.*, December 21, 1885.

Vickery, R. S., *Major and Surgeon*.—Relieved from duty in Department of Columbia, to repair to Washington, D. C., and report in person to Surgeon-General for duty in connection with Army and Navy Hospital, Hot Springs, Ark.—*S. O.* 293, *A. G. O.*, December 22, 1885.

Reed, W., *Captain and Assistant Surgeon*.—Leave extended one month.—*S. O.* 293, *A. G. O.*, December 22, 1885.

ORIGINAL ARTICLES.

HYDROCELE OF THE HERNIAL SAC.

BY THOMAS E. McARDLE, A.M., M.D.,
PROFESSOR OF SURGERY, NATIONAL UNIVERSITY,
AND
LOUIS KOLIPINSKI, M.D.,
RESIDENT PHYSICIAN, CHILDREN'S HOSPITAL, WASHINGTON, D. C.

ONE of us having recently assisted at an operation for hydrocele of the hernial sac, we became much interested in the subject. To our astonishment, upon turning to a well known text-book we were informed that "it is a very rare affection, and that not more than six cases are on record." Further investigation, however, convinced us that the author was mistaken on this point, and that his work would be a dangerous one to place in the hands of students were his other opinions of no more value than the one just quoted, but, as Homer sometimes nods, we are willing to concede that a skilful surgeon may not know everything about hydrocele of the hernial sac, and yet write a work on surgery with as great a claim to infallibility as is given to any mundane matter.

In the hope that the result of our investigations of this subject may prove entertaining and possibly instructive to others, we have embodied them in the following pages, conscious that they too may be open to as full and just criticism as we have taken the liberty of making upon the work of others more learned than ourselves.

Authors have frequently confounded a true hernial hydrocele with a congenital hydrocele, or a considerable effusion resulting from a strangulation, and it is hence difficult to determine to whom really belongs the credit of having first understood and described the true condition. Bell[1] says that Saviard was the first to consider it particularly, which we have not been able to confirm. True it is that Schreger[2] was the first to write a monograph, and one too of great merit. This writer is quoted by Chelius, who incorporated the teachings of the former in his *System of Surgery*. In the list of cases which is appended to this essay we have arranged all genuine instances which we have been able to collect. At the same time, we are aware that we have omitted some, both on account of memoirs which we have been unable to examine and reports which we have felt compelled to exclude because of their ambiguity. It will be evident that to French writers belongs the credit of the publication, not only of the majority of cases, but likewise the majority of clear and logical descriptions. Of recent systematic treatises on surgery, the hand-book of Billroth and Pitha is the only one which does more than note the possibility of occurrence.

Our researches were conducted in the library of the Surgeon-General's Office, U. S. A., and our thanks are due to Dr. Fletcher, for allowing us the use of the proof of the volume of the *Index-Catalogue* containing the subject *Hydrocele*, and to Dr. Wise for continuous kindness in obtaining the works we desired.

Hydrocele of the hernial sac is an acute or chronic condition, due to an inflammatory process, and occurring in a hernial sac the neck of which is occluded.

We use the word hydrocele in this connection not because we think it the proper term; on the contrary, we consider it a misnomer, but it is so commonly accepted by surgeons, that we were afraid of being misunderstood if we employed another title. We think that hydrocele was used to signify the condition of affairs under consideration, from the fact that it was at first misunderstood and mistaken for a true hydrocele, which Percival Pott defines as follows: "The term hydrocele, if used in a literal sense, means any tumor produced by water, but surgeons have always confined it to those which possess either the membranes of the scrotum or the coats of the testicle and its vessels."[1] Dropsy of the hernial sac (*hydrops sacci herniosi*) is a better term, and relegates it to the group of watery inflammatory effusions of serous cavities.

We have said that it is an acute or chronic condition. The latter form, it is true, is not so frequent as the former, and is of much less practical importance. It must, however, be recognized by the demands of etiology. The acute condition is the one of greater moment and is the one which a surgeon would naturally have in mind when speaking of hydrocele of the hernial sac. Its development is sudden and rapid, its symptoms active, its speedy recognition necessary, and its treatment prompt and judicious. When the process has run its natural course, when the patient's only complaint may be the bulk of the tumor, there is no danger of confounding it with hernial strangulation, and the surgeon operates for chronic hydrocele at his convenience.

Dropsy of the hernial sac is due to an inflammatory process, because it is invariably preceded by, or associated with, other organic alterations or effects of increased activity, and because an exciting cause, if carefully sought after, is constantly found. The occlusion of the hernial sac is the very best evidence of a preceding irritation, and, as we shall show further on, the character of the protruding parts, and their liability to inflammation, influence the frequency of its occurrence.

Pathological Anatomy.—According to Velpeau,[2] hydrocele of the hernial sac may occur under three

[1] Bell: System of Surgery, 3d edit., Edinb., 1787, vol. i. p. 461.
[2] Schreger: Ueber Erkennt. u. Behand. d. m. Hernie complicirt. Hydrocelen. Arch. f. med. Erfahr., 1. Bd. pp. 1–44, 1809.

[1] Pott: A treatise on the hydrocele.
[2] Bull. Gén. de Thér., 1839.

different circumstances: 1. It may occur at the same time as the rupture. 2. It may occur after the formation of the hernia. 3. It may occur in an old hernial sac, in which there is no hernia. There are practically two varieties of hernia, in which hydrocele of the sac is found, namely: in oblique inguinal hernia of the congenital or acquired forms, and, secondly, in the femoral variety, but the majority of cases happen in males, and are consequently inguinoscrotal herniæ. Schreger[1] gives four varieties: 1. The prolapsed portions occupy the upper, the hydrocele the lower part of the sac; it occurs chiefly in the congenital inguinal form of hernia. 2. The prolapsed parts fully occupy the sac, the fluid filling the interspaces, and is external to the hernia, but not at the fundus of the cavity. 3. The fluid fills the sac, with a small knuckle of gut or omentum protruding into it. 4. (Original with Schreger) a small hernia succeeds a congenital hydrocele, the hernia not protruding, but contained within the inguinal canal.

Hydrops sacci herniosi is produced by an inflammatory serous exudation from the peritoneal lining of the sac, and the peritoneal coverings of the prolapsed parts. The part involved is essentially the peritoneum, and in order that an inflammation of this tissue should occur to produce a hydrops of the hernial sac, it is necessary that there should be an occlusion of the neck of the sac; an occlusion produced by an adhesive inflammation, constricting the prolapsed omentum into the shape of a pedicle, in which hard fibrous tissue predominates, and in which the original appearance is unrecognizable, though the free, protruding mass possess its normal histological evidences. It is this adhesive inflammation of the neck which on the one hand seals the hernial cavity, and, on the other, spreads to contiguous tissue. Thus, union between the walls of the sac and the inflamed parts often occurs, unless it be that to the solid mass is added a rapidly growing fluid tumor.

The amount of fluid varies from a few ounces to three or four quarts. Its qualities are those of an ascitic fluid, yellow, brown, or red, and it may be still further altered by an accidental hemorrhage or suppuration. The sac may be an empty one. The hernia may have been cured; most frequently, however, there will be found an irreducible epiplocele, whilst a small fold of unstrangulated intestine may also partly protrude and menace the success of a radical operation.

Etiology.—We have mentioned the kinds of hernia in which dropsy occurs, and the usual character of the prolapsed parts when the sac is not empty. It is consequently evident that the male sex, inguinal epiplocele of long standing and adhesion of the neck are predisposing causes. The presence of retained omentum, occluding the cavity, is a common concomitant, and by its broad or globular surface and rigid pedicle, is both liable to suffer inflammation, and to injure the lining membrane through its resistance to pressure or sudden force from without.

As exciting causes, stand prominent: contusions, falls, active exercise, sudden severe efforts, and the irritation of a badly fitting truss. Recorded cases clearly show the development of the disease to have been due to imprudent or careless action, in changing or suspending the use of mechanical means of retaining a hernia, and the appearance of active symptoms to have been associated with the presence of a permanent tumor.

The above are the causes which obtained in the cases described by surgical writers, but we may conclude this section with the general formula of B. Schmidt,[1] that hydrocele of the hernial sac is developed by an accumulation of many irritants from without, or from traumatism, or from the relation of surrounding anatomical parts, either within or without the sac, interfering with the local circulation.

Spontaneity of occurrence will hardly be observed, and a successful search for a traumatic cause will be of prime importance in the diagnosis.

Symptoms.—As we have recognized in our definition an acute and a chronic character of the disease, naturally the symptoms will be considered under two classifications.

The symptoms of a chronic hydrocele of the hernial sac may be comprised in but the single objective one of a large, fluctuating, more or less translucent tumor, occupying the site of a hernial sac, and by its feel, as well as its shape, when pendent, indicating the nature of its contents. We recognize the tumor by the history of its development, and the fact of its relation to a past or present rupture. The patient may feel no discomfort beyond the weight and size of the tumor. Its progress may remain uncertain, and in itself is of no considerable importance.

But in an acute exudation the picture changes. The patient has been subjected to one of the causes which we have mentioned, and his hernia, which could be reduced, has increased rapidly, and cannot be made to diminish in volume by manipulation. There are local heat, pain, and tenderness, locomotion is avoided, and the patient lies recumbent, whilst his general condition is unaffected. There are none of the evidences of a sudden strangulation of the intestine, and the natural course of the process would be disappearance or the chronic state.

On inspection we observe the round or pear-shaped tumor resembling a hernia or hydrocele. By palpation fluctuation is evident inversely as the state of fluid distention, and occasionally it has been possible not only to differentiate the extent and position of the liquid, but also the relation and location of the hernia—epiplocele—by its flattened, fissured, or irregular surface.

Translucency is present in every case of pure effusion.

The symptoms are in no wise obscure, and when they all have been considered the diagnosis is apparent. An error is only liable to occur when we ignore the disease.

Prognosis.—Hydrocele of the hernial sac is not a grave disease, except in so far as it is liable to cause errors of diagnosis Although spontaneous resorp-

[1] Op. cit.

[1] Pitha and Billroth: Handbuch d. Chir., iii. Abt. ii., A. p. 1., 1882.

tion is very rare, the surgeon has at his command a ready means of relieving the difficulty when clearly recognized. The percentage of mortality would be almost *nil* if errors of diagnosis could be completely excluded. It is the diagnostician, and not the operator, who may add to the patient's danger.

Diagnosis.—The diagnosis is easy or difficult, plain or obscure. Hydrops sacci herniosi must be differentiated from simple hydrocele and from encysted hydrocele of the cord high up.

It is to be distinguished from simple hydrocele by the history of the case, by the fact that a previously existing hernia has suffered such an accident as to result in an effusion, also from a knowledge of the evidences which we have given under symptomatology and by the relative location and separation of the fluid tumor and testicle.

Greater difficulty may be experienced in distinguishing it from encysted hydrocele of the cord. But if we take into consideration its size, duration, and relation to a hernia, together with the age of the patient, it ought not be so difficult as some would lead us to imagine. A third occurrence, the possibility of which we must not forget, is, that an undescended testicle may lodge in the neck of a congenital hernia, and that a hydrocele either of the sac or of the tunica vaginalis may arise. Such are the cases that have been described by Mayer[1] and by Jodok Baer.[2] But being aware of its possibility, the absence of the testicle from its normal position would at least lead us to suspect the existence of this complication.

It might occur to mistake it for hernial peritonitis or the false strangulation of Malgaigne,[3] but here the general symptoms are much more apt to be viewed as those of a true strangulation, and whilst hydrocele and peritonitis of the sac both affect the same forms and nature of rupture, the danger of confounding the two would not be of material difference in treatment.

But these are minor difficulties when compared with the importance of recognizing the true state of affairs when hydrops and hernia are both present, for the surgeon is apt to diagnosticate one or the other alone. The diagnosis of hydrocele with symptoms of strangulation is unimportant, for the indication is to relieve the strangulation. Indeed, so important is the strangulation and so completely does it outweigh the hydrocele, that the latter is rendered scarcely worthy of the name of complication.

After the diagnosis of a case of hydrops sacci herniosi it is of primary importance for the surgeon to ascertain the position of the hernia, and if possible its nature. It must be sought in the cavity or in the neck of the sac, where it may be recognized by the greater or less tenderness and fulness of that region. Nor should it be forgotten that the hernia may possibly be secondary and its reduction easily practicable. Let it always be remembered that the dropsy of an old and empty sac is a rare form of the disease, and should not be permitted fully to occupy the surgeon's mind whilst a diagnosis is being made.

Treatment.—Various methods of treatment have been advised and practised for the cure of hernial hydrocele. According as the pathology of the disease has been more or less correctly understood, so has the treatment been more or less correctly defined. Pelletan and Atlee, in whose minds the possibility of active hernial complication prevailed, made the preliminary incisions for a herniotomy. Although not clearly understanding the true condition of fluid, sac, and rupture, which they found, their treatment was successful.

Arnaud, Schreger, and Desault tapped as for hydrocele, and the last further advised the injection of red wine to produce inflammatory obliteration of the sac, and in cases of spurious hydrocele in which there is a collection of fluid produced by local irritation or derived from the abdominal cavity, which may occur in congenital herniæ with patulous cavity, Desault practised mechanical occlusion of the neck of the sac by pressure with a pad preliminary to the injection of irritating fluids. Velpeau,[1] whom we may consider to have had the best practical knowledge of his time on this subject, introduced the injection of tincture of iodine. Later writers on the treatment of the acute variety deferred operative measures and confined themselves to the use of antiphlogistic applications, such as leeches, cold, blisters, and the like, in conjunction with rest. Thus were treated the cases of Curling and Robert.

CASE I. Le Dran: *Obs. in Surg.*, transl. from the French by J. S., 1740.—Hernia of right side descended by degrees to testicle. Bandage applied by Arnaud; hydrocele developed in a month; punctured. Case passed into Le Dran's hands. Arnaud refers to this in his mems. on surgery, and reflects on the supposed conduct of his *confrère*, by which he lost the patient. After several tappings tumor extirpated. Three fluid sacs were found: 1. The proper one of the closed hernial cavity. 2. Between the first and the cremaster muscle, in the cellula of the tunica vaginalis. 3. On the tunica albuginea. He removed the hernial sac and the testicle with the cord, which he could not preserve, being confounded with the cystis hernialis.

CASE II. Monro, Sr: *Med. Essays*, Edin., vol. v., 1742.—An old man; hernia extending almost to knee; violent pain in tumor and loins. Tapped, six pounds of clear serous fluid; then the convolutions of the intestines and the knotty parts of the omentum were plainly felt, but none of them could be reduced.

CASE III. Arnaud: *Mems. de Chir.*, Part II., Obs. xxi. p. 560, 1768.—Female, aged 14; left inguinal epiplocele in labium. In falling, tumor struck; increase in size, and permanent, no pain. Punctured, half ounce of fluid. Author diagnosticated epiploic hydatids from constriction. Mentions cases of a boy and of a woman of 40. Similar treatment.

CASE IV. Pott: *A Treatise on the Hydrocele*, first Am. ed. of his works, Philadelphia, 1819, vol.

[1] Mayer: Verhd. d. phys.-med. Gesell. in Würzb., 1854, '56, '57, vii. p. 130.

[2] Baer: Prag. viertljschr. f. d. prakt. Hlkd. xcii. p. 88, 1866.

[3] Malgaigne: Arch. gén. de Méd., 1841, 3 s. xii. 195-289, and Gaz. de Hôp., 1846, 2 s. viii. p. 446.

[1] Journ. de Méd. et de Chir. prat., t. 35, 1864, p. 396.

ii. p. 110.—Male, aged 25; large indolent swelling in scrotum. Very old rupture, retained at first by truss, replaced by dimity bandage buckled on very tight; in six months tumor not reducible, taxis failing. A still tighter bandage applied, thereupon increase in size with pain and uneasiness. Hesitated in the diagnosis, punctured sac, pint of brown serum; irreducible tumor remained in upper part, and sac refilled with fluid in a year. Incised hardened omentum adherent to neck, cut away the free part, and treated as for radical cure of hydrocele.

Case V. Schmucker: *Vermschte Chir. Schft.*, vol. ii. p. 51, 1779.—Male, aged 40; scrotal hernia of left side for ten years. Badly fitted truss. S. reduced intestine, but not a solid mass (omentum), and applied a truss; hydrocele developed in a month. Laid open sac, one quart of water, and, in all, two pounds of adherent omentum removed.

Case VI. Pelletan: *Clinic. Chirurg.*, t. iii. p. 22, 1810.—Male; right scrotal tumor extending to inguinal ring, testicle at base. Old hernia had increased in size for one or two years. Adherent epiplocele of neck and hydrocele of sac. Operated as for hernia, and union by suppuration.

Case VII. *Ibid.*—Male, aged 62; very old hernia, volume gradually increasing. Colicky pains, local tenderness, no symptoms of obstruction or strangulation, tumor hard at ring, fluctuating below. Operated as for strangulated hernia,

Case VIII. Key: *London Med. Gaz.*, iv. p. 105, 1829.—Male, aged 28; suddenly whilst at hard labor, irreducible epiplocele with acute hydrocele of sac, into scrotum. Became chronic. Fluid drawn off and cavity healed by suppuration.

Case IX. Dupuytren: *Gaz. des Hôp.*, p. 87, 1837.—Refers to a case of Boyer, hydrocele in old hernial sac cured by incision.

Case X. Anonymous: *Bull. gén. de Thérap.*, xvi. 224, 1839.—Male, aged 35; right inguinal hernia of twelve years, partially reducible; by puncture, a little fluid withdrawn, and reduction some time after by non-operative means.

Case XI. Malgaigne: *Gaz. des Hôp.*, 2 s. viii. p. 446, 1846.—Male, aged 70; for twelve years an umbilical epiplocele. Suddenly irreducible, patient neglecting to wear truss or bandage. Local acute symptoms, constipation and distress. Subcutaneous incision, once repeated, evacuated serous fluid. Later lancing, pus. Recovery.

Case XII. Curling: *Pract. Treat. on Diseases of the Testis.*, ii. Am. ed., Philadelphia, 1856—Male, aged 58; transparent painful tumor on left side below abdominal ring, due to a blow. Two years' duration, sudden acute symptoms, leeches, blisters, cure.

Case XIII. v. Dumreicher: *All. Wien. med. Zeitung*, ii. p. 64, 1857.—Male, aged 48; left congenital scrotal hernia. Five months before, increased in size from a kick, with symptoms of inflammation. When these subsided applied a truss for the first time, but did not wear it regularly. Three weeks before admission, again enlarged from overeating and catching cold; pain, constipation, and fecal vomiting. Treated with warm appplications and clysters. When seen was the size of a man's head, and hard, elastic, and fluctuating in spots. In upper part omental pedicle was felt. Normal temperature; bowels open. Cataplasms, etc., subcutaneous puncture, three and a half pounds of dark brown-red fluid, sp. gr. 1.021. Again increased in size, and four weeks after tapping two abscesses burst at fundus. Omentum sloughed away, cavity granulated; recovery.

Case XIV. Duclos: *Gaz. des Hôp*, xxx. p. 270, 1857.—Male, aged 70; double irreducible herniæ. Left epiplocele adherent to neck; right adherent entero-epiplocele, serous fluid. Patient died of abdominal peritonitis from extension of herniary inflammation.

Case XV. Robert: *Gaz des Hôp.*, xxxii. p. 126, 1859.—Male, aged 45; right inguinal hernia, suddenly permanent after unusual exertion. Omentum adherent to neck Symptoms, acute hydrocele. Cured by rest and emollients.

Case XVI. Velpeau's Clinic: *Journ. de Méd. et de Chir. prat.*, xxxv. p. 396 1864.—Male, aged 25; fluctuating, indolent, now transparent tumor, extending to right inguinal canal. Hernia for fifteen years, retained by truss. This breaking tumor partly irreducible, increasing size, no general symptoms, omentum adherent to neck of sac. Punctured and iodine injected.

Case XVII. Nérard: *Mém. et Cpt. rend. de soc. des Sci. Méd. de Lyon*, t. v. pt. 2, p. 251, 1865–66.—Female, aged 35; died of pulmonary phthisis. For ten or twelve years reducible tumor in left labium majus. Before death it enlarged, was permanent and painful. Autopsy showed empty herniary sac full of fluid, and its cavity divided by a band into two compartments, from one to the other of which the liquid could be made to pass.

M. Dron mentions, in the same place, to have seen a similar instance whilst interne. The surgeon performed ablation, and the patient died of peritonitis.

Case XVIII. W. F. Atlee: *Amer. Journ. Med. Sci.*, Oct. 1869, p. 422.—Male, aged 60; right inguinal hernia for twelve years. After a purgative he did not wear his truss; tumor irreducible, large, and hard, bowels constipated. Operated for strangulated hernia; sac contained only serous fluid and gelatinous matter.

Case XIX. Tanfin: *Quelques Consid. sur un cas d. Hydropsie hern. enkyst.*, Strasbourg Thesis, 1869.—Female, aged 56; hernia of right thigh, due to an effort twenty years before. Last ten years wore no bandage. Since then, permanent and indolent. For a fortnight increased size, painless, dull percussion, elastic; no general symptoms. Operated to remove omentum contents. Beside fluid in hernia, a cyst was found in front of sac.

Case XX. Author quotes from Gosselin.—Male, aged 24; crural hernia for six years; permanent for some months. For a week pain and colic; slight increase in volume: fluctuating and transparent. Fluid evacuated; the remaining omentum supported by concave pad.

Case XXI. Holthouse: *On Hernia and other Tumors of the Groin*, 8vo., London, p. 44, 1870.—Female, aged 44; tumor in left groin, size of orange, no pain, dull percussion. For twelve years no truss. Swelling at times painful. Ten ounces

of straw-colored fluid. Sac and omentum extirpated. Recovery.

CASE XXII. Langton: *St. Barthol. Hosp. Rep.*, vol. x., 1874. (Reference furnished by Dr. Ashhurst, Jr.)—Female, aged 50; for sixteen years left femoral hernia, laterally irreducible. Three years before, all replaceable but a nodule of omentum. Growth gradual, and no symptoms. Concave pad, no result. Three pints of straw colored fluid removed, and then repeatedly tapped. Seton introduced into cavity, closed by suppuration. Cure.

CASE XXIII. Duplay: *Paris Méd.*, p. 196. 1875.—Male, aged 33; large scrotal tumor left side. Hernia at seventeen years; irreducible for ten days. Taxis failed; volume increasing, tender, transparent, and fluctuating. Omentum in neck of sac. No general symptoms.

CASE XXIV. G. W. Butler Bryant's service: *Med. Times and Gaz.*, i. 617, 1878.—Male, aged 42; had been frequently tapped for supposed hydrocele on both sides. Hiccough, gastric irritability, constipation, pain and tenderness of right side. Tumor tapped, later laid open, and large mass of omentum, which it contained, cut into, thereby gut incised, and the intestinal wound closed with sutures. The operation was done in Bryant's absence by his assistants. Fecal fistula resulted, and death on the sixth day from general peritonitis. Autopsy showed a right congenital hernia.

CASE XXV. DeBrade: *Etuae sur l'hyd. d. sacs hern. ancien*, Thèse de Paris, No. 94, 1878 (Gosselin).—Female, aged 43; for three years irreducible crural hernia right side. After a long walk, rapid growth and painful: no general symptoms. Rest, cataplasms, punctured, 70 gms. fluid; iodine injection. Epiplocele remained.

CASE XXVI. (Gosselin.)—Male, aged 41; right inguino scrotal hernia for twenty-four years. Did not wear a truss. At thirty, only in part to be reduced. Sudden increase in size, painful, no constitutional symptoms. Treatment and result as in Case XXV.

CASE XXVII. Richet: *Gaz. des Hôp.*, No. 110, September 23, 1879.—Male, aged 24: hernia for eight years; not transparent; omentum adherent in neck and fluctuating below. No symptoms. Complaint of size. Tapped.

CASE XXVIII. Richet: *Rev. Méd. Franc. et Etrang.* 629, 1879.—Male, aged 54; chronic Bright's disease, inguinal hernia suddenly permanent and tender. No symptoms of strangulation. Tapped, 300 to 400 gms. of fluid. Autopsy, mild herniary peritonitis with fibrinous exudation. Intestines could not be reduced, owing to atony, and were found after death occluding neck of sac.

CASE XXIX. J. Ford Thompson: *Maryland Med. Journ.*, xiii. p. 64, 1885.—Male, aged 45: right scrotal hernia for twenty-three years. After effort in working, large, hard, and painful. Fluctuating in front; large, hard mass behind, traceable to external ring. Tapped, but refilled: operated, omentum adherent to neck and cavity; sac removed by dissection. Enlarged testicle and elongated cord extirpated, and more than three pounds of omentum removed. Temporary fecal fistula; recovery.

THE GERMICIDE VALUE OF SOME OF THE VEGETABLE ACIDS.

BY A. C. ABBOTT, M.D.,
OF BALTIMORE, MD.

SOME time since, while engaged in work with Dr. Sternberg, the question arose as to the probable value of the vegetable acids as disinfectants. He suggested the advisability of my conducting a series of experiments with the object of determining whether or not they possessed such properties, and if so, to how great a degree. We take this opportunity of recording the results arrived at.

The method used in the work is the same as that explained in the article on "Commercial Disinfectants" in THE MEDICAL NEWS of Feb. 7, 1885. In order that the conditions should be the same in all our experiments—that is, that we should invariably have the amount of the material to be disinfected, and the volume of the solution of the substance to be tested, equal, it therefore became necessary that those acids which came into our hands in a crystalline form should be made into solutions. For this purpose the following standard solutions were prepared, and all the acids not in a liquid form were tested in this manner.

Standard Solutions Employed.

Acetic acid, glacial.			
Lactic "	concentrated	sp. gr. 1.21	.
Oxalic "	crystallized.	10 per cent.	solution.
Citric "	"	50 "	"
Tartaric "	"	50 "	"
Tannic "	"	50 "	"
Gallic "	"	4.75 "	"

The results of exposing decomposed beef tea, pure cultures of bacillus subtilis, bacillus anthracis, and of pathogenic micrococci, for two hours to the action of these acids, are as follows:

Series No. 1.—Decomposed Beef Tea.

	Active.	Failed.
1. Acetic acid, glacial	20 per ct.	15 per ct.
2. Lactic " concentrated sp.gr. 1.21 .	20 "	15 "
3. Oxalic " crystallized . . .	1.5 "	1 "
4. Citric " " . . .	... "	25 "
5. Tartaric " " . . .	20 "	17.5 "
6. Gallic " " . . .	2.375 "	1.9 "
7. Tannic " " . . .	20 "	12.5 "

Series No. 2.—On Subtilis.

	Active	Failed
1. Acetic acid, glacial	20 per ct.	15 per ct.
2. Lactic " concentrated sp.gr. 1.21 .	20 "	15 "
3. Oxalic " crystallized . . .	1 "	0.5 "
4. Citric " " . . .	... "	25 "
5. Tartaric " " . . .	... "	25 "
6. Gallic " " . . .	... "	2.375 "
7. Tannic " " . . .	... "	25 "

Series No. 3.—On Anthracis.

	Active	Failed

2. Lactic " concentrated (sp.gr. 1.21) .	1 "	0.5 "
3. Oxalic " crystallized . . .	0.25 "	0.1 "
4. Citric " " . . .	1.25 "	0 25 "
5. Tartaric " " . . .	0.25 "	0.125 "
6. Gallic " " . . .	0 7125 "	0.475 "
7. Tannic " " . . .	0.25 "	0.125 "

In recording the results of the experiments, the percentage indicating the activity and failure of the acid tested, refers to the proportion of *crystallized acid* necessary to disinfect.

From the tables it will be seen that bacillus anthracis shows the greatest power of resistance to the influence of these organic acids; second on the list is bacillus subtilis; while the least resistant of the series are the pure cultures of pathogenic micrococci.

From these observations I think it of interest that bacillus subtilis, an organism ordinarily possessed of greater vitality than bacillus anthracis, should succumb, while bacillus anthracis survived the exposure to these compounds. Again, it will be seen that oxalic acid possessed throughout the series of experiments the highest germicide value, while citric acid was comparatively inert; the other members of the group occupying their respective places between these extremes.

NOTES ON THE REPORT OF THE COMMITTEE OF THE AMERICAN PUBLIC HEALTH ASSOCIATION. ON DISINFECTANTS.

By EZRA M. HUNT, M.D.,
of Trenton, N. J.

The Report of the Committee on Disinfectants, recently made to the American Public Health Association, and which has from time to time appeared in the columns of this Journal, is an important contribution to the scientific literature of the subject. It deserves to rank high as the best work of its kind done by the Association or in the country. It is the more important as having been done so soon after similar work by the Local Government Board of England, and as in part, at least, confirmatory of its results. As the report, however, is in some respects not in accord with preconceived views, based upon experiments apparently confirmed in practice, it is well for us to examine the basis upon which the investigation was conducted, and the force of the conclusions at which it arrives.

The authors do not leave us in doubt as to the assumption on which it proceeds. In defining a disinfectant to be only such an agent as is capable of destroying the infecting power of infectious material, it also assumes that *all* of the infecting power of infecting material resides in some one of the microphytes which it is found to contain. It gives no limiting suggestion to the fact that there is no consensus of expert opinion to the discovery of the microphyte of a *single one of the ordinary communicable diseases*. The statement of the last English Report is true that "the bacillus anthracis is the only microphyte of which the morphological characters, life history, and pathological action are known." This, as Dr. Salmon reminded us, does not belong to the ordinary aërial contagions.

The experience of actual conflict with these diseases is also an experience of experts, and we should hesitate before we deny to an admitted *antiseptic* the name of a disinfectant. For it is to be remembered that a real antiseptic, which it is admitted will "prevent the *development* of germs in privy vaults, cesspools," etc., and whose value is "beyond question," is all along spoken of in the report as ranking alongside of deodorizers, and is emphatically denied standing as a *disinfectant*. What we want of a disinfectant is to prevent infectious matter from resulting in disease. If sulphate of iron will do this, it is arbitrary to exclude it as a disinfectant, on the ground that in the culture experiments it did not kill the germ. It may be fair to claim this as the *more radical* test. But admitting that "copperas" will do what it is admitted to do (page 46 of the Report), to claim that it is not a disinfectant is more assertive than is our knowledge about the part played by "germs" in the usual communicable diseases. All the more because even if culture does prove that the microphyte will reproduce the disease, it has not yet been proved that no other part of the dejecta of a typhoid fever patient, for instance, will cause the disease, or what is the part played by the putrefactive products before they have passed to their ultimate changes (see page 113). Even if it were proven that there is no chemistry of disease save that initiated by microphytes, it would be necessary to recognize a distinction between the "parasitic life" and its products. But the "morphological characters, life history, and pathological action" of the microphytes of communicable diseases are not as yet well enough known for us to assume that there are no independent chemical or other causal phenomena of disease.

Such a definition of a disinfectant is still more arbitrary when it accepts as an axiom that, "in the absence of spores, an agent which destroys the vitality of one microörganism of the class to which known disease germs belong, will destroy all other organisms of the same class." What does "*of the same class*" mean, when our classification is so incomplete that anthrax, so different in its mode of propagation from scarlet fever, smallpox, etc., is made to stand for all the rest. Is not this sentence from Dr. Cash (of the Local Gov. Rep., 1884) worthy of comparison: "It does not necessarily follow that because the administration of a given drug may limit the action of one virus, that it will certainly have a similar action upon another. The circumstances and manner of growth, and the power of resistance of the bacilli which are, for instance, the active agencies in the anthrax and in bovine tuberculosis, are probably so widely different that a tissue modification which might be fatal to the propagation of the former, would hardly affect the latter."

The limitation "*in the absence of spores*," is all the more disturbing, because if killing the germ is the crucial test which is to exclude from "disinfectants" articles which prevent their development and prevent decomposition, the definition of a disinfect-

ant which attempts such a test and yet leaves the spore uninoculated and unkilled, is still more arbitrary. We, therefore, are not prepared at present to accept such a definition of a disinfectant. All the more because the field is not yet so clear that the laboratory experiment on non-human cultures can be assumed exactly to represent what takes place in the human organism in the processes of disease. It will be time enough for that, when we have more fully settled the analogical inferences between the lower animals and man; when we have tested these more fully by that close clinical observation and experience, which is also an expert conclusion, with corrected tests, and when we cease to find the world's best biologists and microscopists, after seven years of watching, not agreed whether a microphyte which is a specific agent is a micrococcus or bacillus, or what its shape is (see Klein, Sternberg, Salmon, and others, as to swine plague). On page 21 of the report it is shown, too, how much depends on time of exposure.

We are willing to march on just as rapidly as experiment fortified by experience approves, but not to define a disinfectant by the test proposed until we know that there is no other infection in the world than a microphyte, in all respects corresponding to the particular ones which have been cultured in the investigation. We, therefore, cling to the "good authority" for calling a substance which will *prevent putrefactive decomposition a disinfectant* (page 3), and so accept the ferric and zinc sulphates as such, as also sulphur dioxide. In fact, comparisons of sentences show that the report, although in its introduction excluding all but germicides from the name of disinfectants, does occasionally speak of real disinfectants which are not germicides. Thus page 73, "It is a matter of importance to determine the exact germicide power of this and other agents, which have been proved to be useful disinfectants."

We cannot consent, with the facts in evidence, to the disparagement of sulphur dioxide, as "not a reliable disinfectant for the purposes, and in the manner in which it is commonly applied. The article, No. 7, in the Local Government Board, September, 1884, by J. B. Laws, F.C.S., pp. 204–208, and the observations of Dr. Burdon Sanderson, F.R.S., may well be read as a comment.

Bucholtz, Koch, etc., have recognized *killing* power and *restraining* power as both needing to be considered. It is due to the report to say that its conclusions are not so strict as its working hypothesis, and that on page 87 it holds to sulphurous acid as a disinfectant, although in non-spore material the standard five per cent. solution of sulphurous acid failed to prevent the development of various micrococci, of the bacteria of putrefaction, or of the micrococcus of the vaccine vesicle.

While the reasons given fully vindicated the preference for superheated steam for certain purposes, as bales of rags, etc., in accord with the views of Koch, Gaffky, Löffar, and Dr. Parsons, the ground of preference does not apply when dealing with rooms, etc., in the usual communicable diseases. The same kind of consideration we would give to hydrogen peroxide, and would not accept the dictum which disregards "the promptness with which this agent destroys volatile putrefactive products and *arrests putrefactive* decomposition." The experiments of Dr. Kent, under the direction of Dr. Raymond, where the rooms were tight, seem thoroughly to verify the value of sulphur dioxide and its mingled fumes and acids, for the destruction of insect life, while some good points are brought out as to the relative production of sulphurous and sulphuric acids. Experiments with sulphurous acid gas in solution can hardly be regarded as exactly analogous to what takes place in the burning of sulphur, since sulphurous acid is not the only product, and heat, smoke, and moisture have their influence in the penetration and in the decomposition of the products. No known specific microörganisms were exposed in the Brooklyn experiments with burning sulphur.

The article by Surgeon Smart, on the disinfectant properties of putrefactive products, is a very suggestive one, and quite analogous to a consideration of the disinfectant properties resulting from the *decomposition* of gaseous and acrid products, such as those of burning sulphur. Also note the report of MM. Nicati and Rietsch as to the effects of the fluid ptomaine, being the same as that of the microphyte.

The reading of all of this report, from cover to cover, convinces us of its value, *as also* that there is yet very much new truth to break forth on this subject. As a compendium of what has been done before, and as a record of very many most valuable and instructive biological investigations, conducted by a competent committee, it will be greatly prized and not at all lightly by those who cannot accept it as determining the boundaries of actual disinfection in human diseases.

Every one of the writers and experimenters has done good work, and added to the value of the report. But its conclusions, so far as new, need the most cautious adoption, and, in their present form, are not *en masse* ready for popular distribution. We cannot yet tell either the public or the medical fraternity (page 124) that, in the sick-room, chloride of lime and mercurial chloride only are to be used for spore-containing material, and carbolic acid, sulphate of copper, and chloride of zinc for sporeless excreta, and for privy vaults mercuric chloride and chloride of zinc only. The recommendation of immersion of clothing and bedding in a two per cent. solution of carbolic acid for four hours, does not correspond with the text of the report. Fumigation with sulphuric acid gas, for at least twelve hours, is not to be recommended if it fails to prevent the development of the bacteria of putrefaction, and of some of the micrococci, and if no other agents but germicides are disinfectants. We rejoice, nevertheless, that the report does not discard it. Chloride of lime is still retained where we have always held it. In Standard Solution No. 2, permanganate of potash is unnecessarily added. It is claimed, by the report, "not to be generally applicable for purposes of disinfection." It is very expensive, and, if added for coloring, is easily replaced by the sulphate of copper, or by indigo. There are several valuable suggestions in the conclusions, which, if used to modify somewhat several circulars already issued by State boards, will

improve them, and be much better for general distribution than the forms added to this report.

Did time permit, it would be easier to point out in detail the excellences of the report, than it has been to suggest a few criticisms. It is to the honor of the able Chairman of the Committee that he is as unprejudiced and many-sided as such an expert can be, and ready to respect the views of those who, as close clinical experimental observers and reasoners, have studied disease propagation in its real habitats, hosts, and processes. He has been well aided by a competent committee, and not only the Association, but the medical profession at large, will be grateful for the report, and yet hold its conclusions under experimental and clinical advisement and test.

MEDICAL PROGRESS.

Salicylate of Lithia in Rheumatism.—M. Vulpian has presented, before the Académie de Médecine, the following summary of the result of his researches upon the use of salicylate of lithia in rheumatism:

In acute articular rheumatism and in acute attacks of gout, the salicylate of lithia appears to be as efficacious as the similar sodium salt. The lithia salt is occasionally useful in dissipating the still slightly painful joints left after treatment with the sodium salt.

The forms of acute rheumatism in which the fibrous tissue is especially attacked, respond more readily to the lithia salt, which is also the more effective in subacute progressive articular rheumatism. By the use of the salt last named there has been obtained a noteworthy abatement of the symptoms of chronic articular rheumatism.

The maximum efficient dose of salicylate of lithia is seventy-five grains daily, while sixty grains daily are generally sufficient. Its usual physiological effects are, more or less pronounced headache, vertigo, and considerable deafness, but the buzzing and whistling and other subjective disturbances of hearing, so common after the use of the salicylate of soda, are here comparatively rare.—*L'Union Médicale*, Dec. 10, 1885.

Pyridin in Asthma.—In Professor Germain Sée's clinic in Paris, Rosenblück (*St. Petersburg med. Wochenschrift*) has tried the action of pyridin in various forms of asthma. The nervous and emphysematous forms were rapidly relieved; nausea and giddiness being noticed only once. The presence of bronchial catarrh is no contraindication to the treatment, which was carried out by allowing four to five grammes of the liquid to evaporate from a flat dish in a small room, the patients being exposed to the vapor for one hour and a half three times a day.—*British Medical Journal*, December 5, 1885.

Baths of Permanganate of Potassium.—Hulmann, of Halle, recommends baths of potassic permanganate solution as an excellent remedy in scrofulous exanthema, eczema, prurigo, intertrigo, and as a disinfectant in the desquamative stage of the eruptive fevers. The strength of the solution used is one drachm to the gallon. The patient is washed with soap and water, and allowed to remain in the bath until the fluid used assumes a brown tint.—*Nouveaux Remèdes*, Dec. 15, 1885.

Cadaveric Lesions of the Nervous Centres.—Dr. Baillarger, in *The Annales Medico-Psychologiques*, No. 1, 1885, gives an account of some observations recently made, which tend to demonstrate that the adhesions of the membranes to the cortex cerebri, which are almost constantly found in the brains of patients who have died of general paralysis, are only produced after death, and that they ought, therefore, to be regarded as a cadaveric lesion. In five cases in which examinations were made less than ten hours after death, no adhesions were found.—*Dublin Journal of Medical Science*, Nov. 1885.

Effects of Prolonged Lactation upon the Ovaries and Uterus.—Japp. Sinclair presents the following conclusions, based upon the study of a large number of cases of prolonged lactation:

1. Lactation tends to prevent conception by retarding the return of the ovaries to a condition in which ovulation is perfect.

2. After weaning, the evolution of the ovaries is much more rapid than during lactation.

3. The abrupt cessation of a prolonged lactation may be followed by an evolution of the ovaries and uterus so rapid as to induce symptoms of ovarian and uterine hyperæmia.

4. Prolonged lactation may produce a superinvolution of ovaries and uterus, and under favoring circumstances a prolapse of the latter organ.—*Revue Médicale*, Nov. 28, 1885.

Acute Rheumatism.—Dr. Pepper, in a clinical lecture on acute rheumatism, delivered at the hospital of the University of Pennsylvania, described a typical case of rheumatic fever. Speaking of the morbid principle to which the symptoms are probably due, he said it is held by many that this is lactic acid; his own belief was that it is some complex organic substance, which has not as yet been, and perhaps never will be, thoroughly isolated. The great danger of hyperpyrexia from a sudden failure of the heat-controlling centre is one that ought always to be borne in mind. In his experience, it had generally been associated with a marked tendency to nervous exhaustion, either from the prolonged course of the disease with considerable febrile action, or from worry, anxiety, and depression of spirits. The treatment of hyperpyrexia is of the utmost importance. If salicylates and antipyrin fail to bring the temperature down, the patient must be put into a cold bath. His plan is to put the patients into a bath-tub, and rub them with blocks of ice until they are cool, and the symptoms have passed off, when they are put to bed; he has never seen any injurious results from this plan, and believes he has saved life by it in five instances. —*Med. Times and Gaz.*, Dec. 12, 1885.

Nux Vomica in Rectal Procidentia.—During the past ten years Schwartz (*Il. Farm. Ital.*) has successfully used the extract of nux vomica in rectal procidentia, both in infants and adults, even when the trouble has become chronic. One and one-half grains of the extract are dissolved in eight ounces of distilled water, and

of this from seven to ten drops are taken every four hours. The dose for a child is given as five drops, and for an infant of one to two years the dose is two to three drops. A recent prolapse should succumb in from twenty-four to forty-eight hours. To prevent relapse this treatment is continued a week after cure, the appropriate dose being taken but twice daily. If the prolapse is not of recent date, sixty grains of extract of rhatany may with advantage be added to the original solution.—*Nouveaux Remèdes*, Dec. 1, 1885.

COCAINE IN OPIUM HABIT.—DR. BANNING places on record the following facts with regard to the case of a patient for whom it was prescribed in order to counteract the effects of morphinism. Eight grains and a half of the drug were taken in three days, commencing with a dose of one-eighth of a grain, and increasing up to two-thirds of a grain. No appreciable toxic effect was produced; and the only physiological one was exaltation of the nervous power, followed, in three hours afterward, by corresponding depression. Two or three small doses of morphine only were administered during this period, after which the patient progressed without a bad symptom. The patient had been in the habit of taking from five to ten grains of morphine daily for three years. The cocaine was bought in two parcels, and from different druggists.—*Brit. Med. Journ.*, Dec. 12, 1885.

NERVOUS ALTERATIONS IN THE FEMALE GENITAL APPARATUS.—FREUND has examined, microscopically, the two uterine ganglia of Frankhæuser under various conditions, with the following results:

During pregnancy the ganglia become double their ordinary volume, owing to numerical increase and individual hypertrophy of the component nerve cells. After parturition there is observed a converse process,—a puerperal atrophy, which may be either physiological or pathological. If physiological, there is seen a reintegration of the ganglia; if pathological, there occurs a compression of the nerve cells by an overgrowth of the sclerous element. This is seen especially in abnormal uterine involution and in chronic parametritis consecutive to labor.

In addition, these ganglia, the origin of the major portion of the trophic and other nerve fibres distributed throughout the uterus, may induce, by their alterations, grave uterine malnutrition, and thus is established a vicious circle which explains the tenacity of uterine affections consequent upon delivery.—*Bulletin de Thérapeutique*, Nov. 30, 1885.

ALKALOID OF POMEGRANATES.—A crystalline body has been obtained in minute quantities from the rind of pomegranates, which, when placed upon the tongue or other portions of the mucous membrane, appears to cause a paralysis of local sensation after the manner of cocaine.—*American Druggist*, Dec. 1885.

POTASSIUM IODIDE AND GOOSEBERRY SYRUP.—GÉRARD LAGUE has recorded the useful fact that the acridity of potassium iodide is completely masked when administered in gooseberry syrup.—*Journal de Médecine*, Nov. 15, 1885.

BRIEGER ON PTOMAINES.—DR. BRIEGER, of Berlin, who has for some years been engaged in the investigation of ptomaines, has just given to the world, in a pamphlet of 83 pages, the results of his latest researches. These have been directed to the determination of the ptomaines which make their appearance in the human body after death, in order that he might the better distinguish such as are the product of pathogenic bacteria. He has added to those already known, viz., neuridin and cholin, no fewer than five hitherto undescribed. His observations show that in each successive stage of animal decomposition, new basic bodies are found; that some ptomaines disappear, others taking their place, while some found at first very sparingly become more abundant as putrefaction proceeds. So soon as life is extinct, lecithin begins to break up into its proximate constituents, and by the third day neuridin appears, always accompanied by some cholin, but neither of these has any great toxic power; only after they have disappeared do the highly poisonous bases come into existence. The later ptomaines which Dr. Brieger has identified he calls cadaverin, saprin, putrescin, trimethylamin, and mydalein, which, however, are far from exhausting the whole series of cadaveric ptomaines. Dr. Brieger believes that pathogenic bacteria, like those of simple putrefaction, generate ptomaines out of the organic fluids in which they multiply. He conducted observations on the typhus (enteric) bacillus of Koch and Eberth, and was repeatedly able to isolate a ptomaine which was extremely fatal to guinea-pigs; and, turning to septicæmic poisoning, he was in like manner able to connect the origination of the toxic substances in the pus of a psoas abscess in a girl of nineteen years, which ended fatally, with an organism described by Rossenbach as the Staphylococcus Pyogenes Aureus, the poison in this case being a hydrochlorate of a ptomaine. Dr. Brieger's are the first researches of the kind conducted on strict scientific methods, and it is to be hoped that he will, before long, indicate some practical application of his results in the field of forensic medicine no less than of pathology.—*Med. Times and Gaz.*, Dec. 12, 1885.

TEST FOR HEMATURIA.—LUCHINI (*Bollet. Farm.*) recommends the following method for the determination of the presence of blood in urine. It is self-evidently not so delicate as spectroscopic or microchemical analysis, but it has the merit of being easily applied.

To three drachms of the suspected urine are added one drop of strong acetic acid and one drachm of chloroform. After agitation, the chloroform, which sinks to the bottom of the tube, will be more or less tinged with red if blood in noteworthy amount be present in the urine.—*Nouveaux Remèdes*, Dec. 15, 1885.

A CASE OF AUTO-CÆSAREAN SECTION.—The following almost incredible history is communicated by DR. GUGGENBERG, of Meran. Some years since he was called to a woman, thirty-seven years of age, who was taken in labor with her eighth child. After suffering great and ineffective pains for two or three days, the woman, believing herself on the point of death, took a razor and ripped open her own abdomen, extracted a dead child, divided the funis, and removed the placenta. When Guggenberg arrived he stitched up the

wound, and after a short period the patient recovered, and has since enjoyed excellent health. Guggenberg exhibited the woman at a meeting of German practitioners, held at Tetschen, and expressed his opinion that an incomplete spontaneous rupture of the uterus had taken place and that the woman had not penetrated the organ with the razor. The case was further remarkable, inasmuch as although the hemorrhage was at first profuse, it gradually afterward spontaneously ceased, and although a large quantity of the intestines prolapsed and were replaced with great difficulty, the recovery progressed rapidly.—*Provincial Med. Journ.*, December, 1885.

Naphthalin in the Treatment of Ulcers.—According to Dovodtchikow (*Wratch*, 25, 1885), naphthalin forms a most valuable local application to ulcers, especially in patients of the poorer class. Apart from its cheapness and the ease with which it may be applied, it is recommended as inducing rapid healing and cicatrization, and as possessing such antiseptic properties as to cause the rapid disappearance of offensive odors. A still more important claim is that the application is absolutely painless and non-irritant, so that the patient thus treated may continue his work without retarding the cicatrization of the ulcer.—*L'Union Médicale*, Dec. 12, 1885.

Orthophenylsulphurous Acid: Aseptol.—The following conclusions are from a report lately presented before the Belgian Academy of Medicine by M. Anlssens:

1. Aseptol differs from carbolic and salicylic acids in that it is soluble in water, alcohol, and glycerine in all proportions.

2. Though more strongly acid than is carbolic acid, it is infinitely less caustic.

3. It is non-fermentiscible, and possesses to a superior degree the antiputrescent and disinfectant properties of carbolic and salicylic acids.

4. The substitution of aseptol for carbolic acid is recommended in all exigencies of prophylaxis and disinfection in public and private hygiene.—*Revue de Thérapeutique*, December 15, 1885.

Corrosive Sublimate in Conjunctivitis.—Below has placed on record 65 cases of conjunctivitis (26 simple, 19 pustulous, 2 diphtheritic, 2 gonorrhœal, and 16 granular), in which solutions of bichloride of mercury (1 : 2000) were used. From the results of these observations, Below draws the following conclusions:

1. Under this treatment, the diminution of the secretion, both in chronic and acute conjunctivitis, and the decrease of the hyperæmia, are more rapid than in the similar use of nitrate of silver.

2. Simple phylctæna, thus treated, disappears as rapidly as under the use of calomel.

3. The use of a weak solution of bichloride of mercury in spray yields good results as a prophylaxis of gonorrhœal conjunctivitis in the newborn.

The sponging is practised two to eight times daily, and the inner surface of each lid is separately subjected to the action of the solution.—*L'Union Médicale*, Dec. 12, 1885.

Reflexes in General Paralysis.—After a review of the literature of the subject, Bellencourt-Rodrigues (*L'Encephale*, 1885) presents his personal studies of the condition of the reflexes in 68 cases of progressive paralysis.

In 43 cases an increased knee-jerk was present, although two of these were pronounced ataxics. In the remaining cases the reflex was normal.

The plantar reflex was absent in 22 out of the 68 cases; and of these, 16 exhibited increased patellar reflex, in 4 there was absent plantar reflex with normal patellar reflex, and in 2 both of these phenomena were absent.

The author emphasizes the fact that the patients with increased patellar reflex and practically absent plantar reflex, presented otherwise only psychical symptoms without disturbances of speech, and inclines to the belief that the condition described is pathognomonic of incipient paralysis.—*Centralb. f. d. med. Wiss.*, December 5, 1885.

Kostyleff on a Case of Hydrophobia Treated by Inhalations of Oxygen.—In the *Meditz. Oboz.*, Fasc. 24, 1884, p. 1077, Dr. B. Kostyleff, of Tver, furnishes details of an interesting case of hydrophobia in a railway guard, aged 63, of drinking habits, who had been bitten by a suspicious dog about four months before his admission. The wound having rapidly healed, the patient remained well until August 5, when there appeared extraordinary sexual excitement (which remained up to his death), headache, general malaise, loss of appetite, and thirst; and two days later, hydrophobia with pain in the throat. When brought to the Zemsky Hospital, on August 8, the patient suffered greatly from respiratory and pharyngeal spasms, which occurred almost every minute; he spat out frothy saliva with admixture of blood, and labored under intense general excitement with delirium of persecution. Following the instance of Professor Lashkevitch, Dr. Kostyleff gave trial to the oxygen treatment. The effect was most striking. After the first few inhalations, respiratory spasms and salivation disappeared; the lips, which had been cyanotic, turned rosy; the patient became calm, and soon requested to eat, drink, and smoke. Being extremely gratified with the results, the patient did not for a moment part with the inhalatory tube, and during the first day inhaled about twelve cubic feet of the gas. He slept quietly for one hour and a half in the night, but then a severe paroxysm of dyspnœa supervened, which was cut short by reassuming the inhalations. After a chloral enema, he again fell asleep for several hours, and afterwards was able to swallow two or three glassfuls of tea and milk. He was able often to drink also during the next day; but intense delirium set in, the patient ceasing to recognize the surroundings, and stubbornly refusing to inhale oxygen. Still, he inhaled by snatches about five cubic feet of the gas. On the third day he was steadily sinking from exhaustion, and on the fourth day he died from failure of the heart and respiration, remaining unconscious and delirious up to the end. On analyzing the case, Dr. Kostyleff states that, while not believing in the curability of hydrophobia by oxygen (or by anything), he will still pursue the same treatment in every similar case, since it relieves the patient's sufferings both rapidly and powerfully.—*London Med. Record*, Dec. 15, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 9, 1886.

SCRAPING OF THE UTERUS FOR THE REMOVAL OF RETAINED PARTS OF THE OVUM.

FELSENREICH has recently, in three successive numbers of the *Allgemeine Wiener medicinische Zeitung*, strongly advocated early removal by direct means of any parts of the ovum that may remain in the uterus after an abortion, or after labor either premature or mature. The treatment he recommends is not beyond criticism, for many may think it, in some parts, too prompt, too active, and too heroic. Nevertheless, his article is one of considerable practical value, and to some of the points presented in it we desire to call the attention of our readers.

Felsenreich illustrates, by two very striking cases, the fact that a part of the placenta, or of the membranes, may be retained for weeks or months in the uterus, receiving a partial nutrition, and remain relatively "fresh." One of the cases is quoted from Boeters, and relates to a woman who, nine months after an incomplete abortion in the second month of pregnancy, was attacked with severe and persisting hemorrhage from the womb, which ceased upon the removal of a retained fragment of the ovum. The second case was that of a strong, hard-working woman, who miscarried in the fourth month; the bleeding ceased on the first day; the fifth week after the accident a physician was consulted because of the continuing "lochial secretion," and he found a carcinoma, the size of a small apple, involving the vaginal portion: this carcinoma was supposed to be the cause of the abortion. The tumor was removed by the galvanocautery, and the patient was well in three weeks. Four weeks after the operation she had uterine hemorrhage and severe pain; the flow of blood could not be from the wound made in amputating the cervix, for that had completely healed, but its cause was found to be a fragment of the placenta only as large as a nut, which had been retained for several weeks, without any indication of its presence prior to this hemorrhage.

After presenting these cases Felsenreich states that, according to his experience, there is no benefit to the patient in waiting longer than two days for the discharge of retained portions of the ovum, their spontaneous expulsion seldom occurs later, and with every hour's delay the probability of decomposition and the dangers of septic infection increase. He holds that even two days is too long if the patient lives at a distance from the physician, that the delay should be for but a few hours, and that only in case of near and readily available help is the expectant treatment to be pursued. Thus a time indication for interference in incomplete abortion, or labor, whether premature, or mature, is given.

We think the author is mistaken in including either of the varieties of labor, so far as active interference is concerned, with abortion, and establishing a common time rule for all. The indication for the prompt removal of any portion of the ovum that may be retained is much greater in labor than it is in abortion; moreover, the means by which in most cases the uterus is freed from placenta and membranes, should there be delay, are chiefly external, but this is not true when fragments of the ovum must be gotten rid of after an incomplete abortion. Moreover, we do not believe that, in the majority of cases of incomplete abortion, nature's activity is limited to two days, but that very often after this time the process is completed without detriment to the patient, if proper care be exercised. How much better off would either of the patients referred to have been, had some practitioner of an exploring mind thrust curettes or Simon's spoons into the uterine cavity, groping blindly for some lurking membrane, or loitering placental fragment, when no symptom pointed to their presence? The retention in either of these cases, though it lasted very much longer than two days, did not find expression in decomposition and septic poisoning. These cases testify quite as strongly in favor of the expectant treatment as of any other.

In the removal of retained fragments of the ovum, Felsenreich strongly recommends the digital method, and describes the introduction of the finger into the uterine cavity when the cervical canal is sufficiently dilated. But if the dilatation be not sufficient, Schröder has recommended splitting the cervix as far as the vaginal junction, and after emptying the uterus, stitching the cut parts together as in trachelorraphy, or Emmet's operation. The conservatism of the profession must assert itself somewhere, and we are happy to state that no one has yet proposed

gastro-hysterotomy in the treatment of incomplete abortion.

Felsenreich, after referring to different methods of dilating the cervical canal, such as sea-tangle, sponge, and tupelo tents, etc., gives his preference to the hard-rubber dilators of Hegar, especially because antisepsis can be more readily used with these. In the application of Hegar's dilators assistance will be needed, and narcosis is also usually necessary. Where scraping out the uterus—*raclage*, or curetting—is required, four sizes of Simon's spoons are provided, also two of Bozeman's, or Museux's forceps, a uterine catheter, an irrigator and catheter, dressing forceps, an iodoform *bacillus*, iodoform gauze, cotton, and a two and a half per cent. solution of carbolic acid. The patient lies upon her back across the bed, and the operator sits or kneels between her knees. The vagina is first disinfected, after emptying the bladder, and the uterus is also washed out with an antiseptic solution, if putrefaction has occurred. No speculum is used, but the fingers guide the forceps so as to seize the anterior lip of the vaginal portion, and the uterus is then drawn down, when a Simon's spoon is introduced, and the inner surface of the organ scraped, especially at the fundus, and at the angles at the entrance of the oviducts. It may encourage the timid to know that should the spoon penetrate through the mucous membrane, the operator, and sometimes the assistants too, may hear the sound, and, according to Hegar, will be advised of the fact by a grating bruit caused by contact of the instrument with the muscular tissue. Felsenreich states that in only one case in which, twelve days after a woman had been delivered of a mature living infant, but who had retention of part of the placenta, it was necessary for him to use the spoon, was this peculiar grating or creaking recognized.

After the removal of all fragments by the spoon, Hegar disinfects the uterus, and applies to the interior a five to ten per cent. solution of carbolic acid, or a strong tincture of iodine, a solution of chloride of zinc, or even strong nitric acid: such applications hasten uterine involution, and prevent the return of fungous endometritis. Felsenreich washes out the uterus with a solution of carbolic acid, introduces into its cavity the iodoform rod, and into the vagina iodoform gauze. He narrates six cases in which he carried out his method of treatment successfully, but each one manifested urgent symptoms arising from incomplete abortion, or from imperfect deliverance, such as would have led the most conservative to resort to active interference, though that interference might not have been in all respects such as he has described.

Pajot has said that German wombs are very complaisant, and should he read Felsenreich's paper possibly he will repeat more emphatically the observation. Nevertheless, better the treatment of cases of incomplete abortion so generally followed in Germany, than to let these poor patients perish with septicæmia.

But when should interference take place? If a part of the ovum be retained, and it cannot be immediately removed without violence, and there be no hemorrhage, most practitioners think it wisest to wait. But at the moment that either hemorrhage or offensive discharge occurs, the time for prompt action has come. Possibly, if there be only hemorrhage, nothing but antiseptic tamponing of the vagina and a few doses of ergot will be required. But if the hemorrhage persist, or if the flow be offensive, no matter if constitutional infection has not yet manifested itself, the uterus must be emptied at once. Dilatation of the cervical canal, promptly done, is better and safer than that which requires hours for its accomplishment, and hence Hegar's dilators are to be preferred to any of the tents so commonly used. After the dilatation, let the fragments of the ovum remaining in the uterus be removed, if possible, by Emmet's curette forceps, or one of the wire curettes; if one fails with these, we think that Récamier's curette, notwithstanding the bad name that has been given it, is quite as safe an instrument to use as is a Simon's spoon. During this removal careful antiseptic means should be employed, and afterward the uterine cavity must be thoroughly swabbed with Churchill's tincture of iodine.

DEMENTIA PARALYTICA AND SYPHILIS.

IF statistics are worth anything, we must regard syphilis as a most important factor in the etiology of two very common diseases of the nervous system, tabes dorsalis and general paresis. The very frequent association of the former with previous syphilis is now generally recognized, but it is only of late years that attention has been called to the remarkable number of general paralytics in whom a history of syphilis can be obtained.

English writers do not appear to have especially noticed this association, but recently continental authors have taken up the subject, and a few months ago there was an earnest discussion upon it at the Berlin Medical Society. MENDEL appeared as the chief upholder of the view, and quoted figures which are certainly very suggestive. Thus, of his own cases, in 75 per cent. there was a history of previous syphilis; in Snell's, 75 per cent.; in Romell's, 77.2 per cent.; in Wahrendorf's, 50 per cent.; and in Förstner's, who is opposed to a belief in the connection between syphilis and paresis, 32 per cent. Such statistics indicate either grave errors in collecting the facts or else that syphilis is so common that the high percentage among paretics is of no special significance, but that this latter is not the explanation

is shown by a comparison of the percentage of lunatics having a history of previous syphilis, which Obersteiner found to be only four per cent., with cases of general paralysis, of which there were 21.6 per cent. among his patients. Lange also found among his paretics 33 per cent. with a history of syphilis, while among the other lunatics the number of those who had had syphilis was only 2 per cent.

Westphal professes no faith in the value of statistics, and in general paralysis, as in tabes, does not think that syphilis stands in an etiological connection with the disease. The absence of all traces of syphilitic lesions in the bodies of persons dead of general paralysis, is to him conclusive evidence against the view. Reinhardt, of Hamburg, in 170 cases did not find one with syphilitic lesions in the brain or its membranes, though there were twelve with such lesions in other parts of the body. Admitting the fact that persons who have had syphilis are more prone to general paresis, there is still the difficulty of explaining the precise relationship between the diseases. The changes found in the brain and cord in dementia paralytica are no more specific —*i. e.*, syphilitic—than are those of tabes, and the picture is quite different from that of recent cerebral syphilis. Mendel, however, does not regard the lesions inducing the paralysis as syphilitic, but holds that there is a specific arteritis of the smaller vessels which gradually leads to the changes in the substance of the brain. If this be the case, we should expect to find occasional examples of genuine cerebral syphilis, but Reinhardt's studies of 170 autopsies demonstrate that the specific lesions rarely if ever occur.

The question is one of local interest, as a few weeks ago the columns of the public press contained a full account of an autopsy upon a prominent actor, in whose case there had been difference of professional opinion as to whether the disease from which he was suffering was dementia paralytica or cerebral syphilis. The lesions were certainly those commonly met with in the former disease, but we allude to the case now, solely for the purpose of protesting, in the interests of professional decency, against physicians pandering to a debased public taste, and allowing themselves to be made the tools of sensational news reporters.

It is time that honorable physicians set their faces against this ever-increasing habit of furnishing representatives of the press with details which satisfy no public purpose, but which simply minister to the morbid longings of a prurient and gossip-loving public. In this irreverent generation, the almost sacred character of the relation of the physician and patient has come to be lightly regarded, and the modern reporter, with an assurance strengthened by success, asks for, and expects to obtain, information of the most private nature. That he should so often procure it, is a sad evidence of degeneracy in the profession, and of the neglect of that most important section of the Hippocratic oath, which says: "Quæ vero inter curandum, aut etiam medicinam minime faciens, in communi hominum vita, vel videro, vel audiero, quæ minime in vulgus effevri oportent, ea arcana esse ratus, silebo.

A PAINLESS ESCHAROTIC.

MR. C. E. JENNINGS has recorded in the *Lancet* for October, 1885, two cases in which he used cocaine to alleviate pain, whilst caustics were applied to cancerous growths. One patient was aged 73, and suffered from extensive scirrhous ulceration of the right breast. The surface of the ulcer was covered with rugged, irregular granulations, which bled upon pressure; the veins around the growth were much engorged and the pain was increasing. After painting the ulcerated surface with a ten per cent. solution of hydrochlorate of cocaine, a paste was applied consisting of cocaine, potassa fusa, and vaseline. After some minutes a burning sensation was experienced; then the paste was quickly removed with the charred tissue, by means of pledgets of cotton-wool previously moistened with water. The denuded surface was again painted with cocaine solution, and the compound paste reapplied. By this means, more than a tablespoonful of cancerous growth was removed by a rapid and painless process. The next day a clean, smooth, and bloodless surface, insensitive to the touch, was presented. By this means, most of the scirrhous mass was removed after a few applications. In the second case, the author destroyed a cancerous growth of the os and cervix uteri, by means of sticks of potassa fusa, and a ten per cent. solution of cocaine.

The suggestion that cocaine could with advantage be added to escharotic mixtures, originated with RANDOLPH and DIXON, who published, in THE MEDICAL NEWS of January 24, 1885, an account of their experiments. For the purposes indicated, the advantages of the combination they recommend, as compared with the simple painting, with cocaine solution, of the tissue to be destroyed, are at once evident:—indeed, in the case of the uninjured skin, such painting with cocaine alone is practically without result. As a painless cutaneous application for purposes of counter-irritation, much, apparently, is to be expected from the admixture of cocaine with the acid or caustic employed.

INTRAPARENCHYMATOUS INJECTIONS IN PNEUMONIA

THE treatment of inflammation of the lung by the injection of remedies into its substance has been attempted by LÉPINE, of Lyons, who reported some months ago a rapid improvement, both local and general, under this method. He employed at first a solution of the bichloride of mercury, 1 to 40,000, of

which 20 or 25 cubic centimetres were injected, with the immediate effect of a diminution or disappearance of the râles and blowing breathing, and within twenty-four hours a reduction of the temperature with improvement in the general symptoms. Resolution set in a few days after the defervescence, and convalescence was rapid.

In the *Revue de Médecine* of December 10, he reports a case which was treated by injection of the iodide of sodium, 25 c.c. of a solution of 1 to 25. The patient, a man aged sixty, in a bad condition of health, had a chill on the evening of the 11th, and on the 13th was brought to the hospital with signs of inflammation of the left base. On the 14th, fifty hours after the chill, injections of the solution were made at three different points below the angle of the scapula. Very slight improvement followed, and on the morning of the 15th two other injections were made of 30 c.c. each. Defervescence took place in the night, within four days from the onset of the disease, and by the eighth day resolution had set in. No other treatment was employed, except in the early stages. When the disease is advancing, we should regard this method as of very doubtful value. It is quite possible that the extension of the process might be limited by the injections, but when hepatization has been established in an entire lobe, it is very unlikely that such a small quantity as 25 c.c., when injected in several places, could have much influence upon the process. Indeed, in the report of the cases referred to, it is stated that resolution did not set in for several days after the subsidence of the symptoms, and the improvement may, perhaps, be attributed to the general effect of the drug, and not to its local action upon the lung.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, December 21, 1885.

THE PRESIDENT, CHARLES A. LEALE, M.D., IN THE CHAIR.

DR. J. R. MACGREGOR read a paper on

INSANITY AND PUBLIC OPINION.

In former times, he said, when not only society in general, but even those whose attainments were of such a character as to entitle them to be looked upon as leaders in opinion, had not become emancipated from the thraldom of tradition, the occurrence of insanity was supposed to be occasioned by the direct influence of the Deity; so that the unfortunate subject was considered, for some unknown offence, to be laboring under divine displeasure, and suffering punishment in consequence. Such unfortunates were regarded with aversion, and usually consigned to chains and dungeons, where, whatever might have been their chances of recovery under favorable conditions, they were effectually excluded from the benefits which might have been derived from appropriate treatment. Mental derangement being thus regarded as a direct dispensation of Providence, it was not expected to be understood; hence, inquiry was discouraged at the outset, and hope of recovery considered out of the question, except under the unlikely operation of the same power which induced the catastrophe.

A somewhat similar state of things characterizes the theory that the mind can be disordered as a separate entity, and the practical effects of this view are hardly different from those of the one first mentioned. Having no knowledge, and there being no means of acquiring any, of the nature of mind as an independent principle, unconnected with the instrument of its material manifestation, it is apparent that all attempts to reach this principle or modify its qualities, will be to no purpose. Notwithstanding the advances which have been made in our knowledge of insanity, there is in the community too large a percentage of men who, intellectually considered, from custom or organization, are, like a blind horse in a mill, satisfied with the same dull round. The evil effects of such deficiency are apparent, not only in the crudities and errors which are adhered to as established truths, but they present themselves as obstacles to that advance which would enable the insane to be better cared for, and insure a larger percentage of recoveries. A very large amount of proof could be advanced in support of this statement, showing how greatly those in charge of the insane are handicapped in their endeavors to relieve this class of patients by the mistaken zeal of the community.

A very prevalent idea is, that every asylum contains a large number of inmates who do not labor under any mental affection. This must necessarily involve the inference that the superintendents are deficient in principle, and consequently unworthy of their positions, and that a collusion on the part of hospital managers, with motives which are none of the best, can be effected. The consequence is, that the suspicious element in the common mind can easily be aroused, and made to follow the direction of any one bold enough to lead, and plausible enough to enlist its sympathies for a seemingly good object. It is only necessary to declare that the sacred right of liberty has been infringed. Popular clamor assumes sway and cries out for retribution; and there are never found wanting those who, either for the emolument to be gained or the *éclat* that will follow, stand ready to embark in the enterprise.

Notwithstanding the general prevalence of the idea that the practice of confining in asylums persons who are sane is a common one, the facts, where it is possible to ascertain them, go to prove that it is not well founded. Some six or eight years ago this subject was agitated in Great Britain, and Parliament appointed commissioners who were empowered to visit every asylum, both public and private, throughout the kingdom, and personally investigate every supposed instance of unjustifiable confinement. This order was executed with minute thoroughness, but the commission was unable to discover a single well-authenticated case.

That there are such things as asylum abuses, no one pretends to deny. But that both their frequency and character are greatly overstated, is equally true. The announcement of a circumstance of this kind, served

up by the press with the exaggerated force of a dramatic tone and coloring, will hardly fail in carrying the multitude; and the construction put upon it is also very wide of a logical deduction, viz., that it is inseparably connected with the system. A single instance is sufficient to array the sentiments of the public in an attitude of hostility toward all asylums; which, when once assumed, it is very difficult to change. A careful inquirer, with unbiassed mind, taking nothing for granted, and willing to devote himself to an extended investigation of this matter, will find, as he proceeds, that the magnitude of such an evil will steadily diminish in its proportions. Whenever these evils do occur, it will also be found that they are confined, for the most part, to those institutions which, from their construction and appointments, are not such as are adapted to carry out the highest needs of the insane. The very large establishments usually built in our municipalities for the insane poor, where immense numbers are congregated, are run on so cheap a scale that the individual cost per patient is scarcely greater than that for the inmates of almshouses. The wonder is that in these establishments, with the resources available, they succeed in doing as well as they do. Complaints of ill usage are very seldom made against private asylums, or those governed by private corporations, where such rates of charge are made as will command the best arrangements for treatment, and the highest order of service. In this connection Dr. MacGregor quoted the following passage from one of the annual reports of Dr. Luther V. Bell, formerly Superintendent of the McLean Asylum at Somerville, Mass.: "There is no such thing as a just and proper curative or ameliorative treatment of the insane in cheaply constructed and cheaply managed institutions; but, to do the greatest amount of good to the insane, the mind of the taxpaying community must be trained to understand and admit the necessity of expensive arrangement, and that, if it is worth while to have any institutions beyond those receptacles in which the most patients, or rather the most sufferers, can be crowded together at the least charge, it is worth while to establish such as will accomplish all of cure or relief which is practicable."

A vulgar opinion exists to some extent, that any person of ordinary intelligence is as capable to judge of the insanity of a patient as the most experienced hospital director; though it is difficult to understand how such a notion can be rationally entertained. A case, illustrating this point, which came under his notice, was related by Dr. MacGregor.

There is, probably, no point connected with insanity which elicits a greater popular interest, while at the same time there is hardly any other on which the public mind needs remodelling, than the knowledge of its causes. As it is a very common error to suppose that every remarkable event is preceded by one equally remarkable, the irresistible tendency which the public manifests on this subject is to seek for some prominent circumstance which has gone before, and assign to it, in conjunction with the after-phenomena, the relation of cause and effect. In reality, the causes of insanity are varied and diverse, covering a wide range of conditions, and often hidden in deep obscurity. In the vast majority of instances, there will be found in tracing the causation a variety of circumstances to be taken into consideration: some, to the trained mind, easy to discover; others, difficult of appreciation, and only to be discovered after long observation. It often happens that manifestations which are regarded as being of the greatest significance are subsequently found to have had less to do with the development of an attack of insanity than some obscure diseased cerebral action which, although imperceptible at the time, proved none the less real. Yet when a case occurs under our notice, the first question propounded by those interested in the patient will probably be, "What is the cause?" and we may run the risk of damaging our reputation for professional sagacity if we do not have ready at hand a prompt and specific answer. The friends of the patient are prolific in their views of the case, and these are often advanced with a degree of confidence from which the most experienced alienist would shrink. To show the unreliability of such opinions, and their entire lack of any philosophical discrimination, it is only necessary sometimes to place in apposition the opinions of two sets of friends, who, either with opposing motives, or regarding the same condition from different standpoints, reach conclusions which are directly antipodal; each side, in the meanwhile, remaining satisfied that it has reached the correct conclusion. The statistical tables appended to the reports of asylums, in which the causes of the disease are individually noted, are, no doubt, largely unreliable, because the information upon which they are based is derived chiefly from this class of people.

The tendency is, in general, to run after the marvellous, and such kinds of information as will produce a painful, rather than a healthy impression on the human mind; and this has often led the social reformer, in the pursuit of his favorite hobby, to manipulate the truth in a manner favorable to his project of uprooting some special evil existing in society—some particular vice or practice, such as intemperance or sexual indulgence, with the suppression of which the earthly millennium is expected to come. It may be said in regard to these vices, however, that although they unquestionably hold their place in the causal list in varying degrees of influence, it often becomes a question as to what is the true relation that they bear toward the disease—how much they may be considered as causes or symptoms of development, or even as the results of the disease. It is generally understood that hereditary tendency occupies the first place in the list of causes; but if asked to specify what influences are most potent in developing the disease, we would be likely to say, those which produce their effect upon the emotional faculties. A proper appreciation of such influences constitutes an important part of that education of which the public mind stands in need.

There is another topic relating to this inquiry, which, if rightly apprehended, would tend to uproot a vast amount of prejudice, and practically redound to the welfare of the afflicted subjects. It refers to the curative measures which are most appropriate. There is no method so likely to produce a favorable result in the shortest time as the early removal of the patient to a hospital; but in most cases, unless the violence of the attack calls for immediate seclusion, recourse is had to almost every other available expedient; generally with a loss of valuable time that diminishes the patient's chances of recovery. Those interested are

loath to recognize that, so long as a patient is allowed to follow the bent of his own will, he is only fostering and strengthening the morbid processes going on in his brain; and that while he remains amid the surroundings of his home, there are constantly brought to his notice objects and scenes intimately associated with the development of the disease, which not only keep alive, but tend to aggravate the morbid action. Antipathies to hospital treatment have occasionally led some to the experiment of retaining patients whose means would warrant it at home in apartments arranged for the purpose, with the assistance of kind attendants. This enables them to have access at all times to the patient, and prevent any harshness of management, while at the same time it is supposed to furnish all the advantages of an insane hospital.

In a hospital for the insane, however, the proper conditions for intelligent treatment can be most effectively fulfilled. The persons engaged in the service become gradually acquainted with the ways of the inmates, and they acquire many arts of management and a degree of skill in the performance of their duties quite unknown to the outside world. Moreover, the medical man concentrating his attention upon a specialty, and devoting his whole time to its study and observation, gains an amount of practical information on the subject of insanity which he could not obtain in any other way. The routine habits of the establishment tend to insure a more quiet demeanor, and a disposition on the part of the patient to be compliant to the wishes of others; and also to induce within himself the effort not only of self-control, but also to cultivate the power of repressing extravagance of thought, and keeping the emotions in subjection to the dictates of judgment.

The domestic management of the insane is defective in another important particular. There is a point in the convalescence, after the stage of excitement has passed away and the delusions have become dispelled, when the mind appears rational in all respects. To the skilled observer, however, complete restoration has not yet been attained. The exhausting effects of the disease upon the brain have not altogether vanished; and a certain period of time must elapse before this result is reached. In an institution, this period is as carefully attended to as the others. The recuperating faculties are kept within the limits of a judicious exercise, and in ways that are conducive to complete restoration. In the domestic management, on the contrary, this condition is the signal for the removal of all restrictions, and the patient is permitted to return to his former habits. The sequel often proves that the experiment was too much for his powers. The morbid process is reproduced in perhaps more than its original severity; and it is only after weeks or months of treatment, if ever, that the patient regains the ground that he has lost.

It is scarcely within the bounds of reasonable expectation to look for any rapid change of public sentiment in these matters, so little disposed are men to relinquish notions when once acquired; and we must be content to await the slow process of a gradual cultivation among the people. Yet it is within the province of each one who is actuated by a conviction that springs from honest inquiry to use his best efforts toward the establishment of an enlightened public opinion.

DR. JOHN DWYER said that the writer of the paper might have laid even more stress upon the fact that sane people are rarely confined in insane asylums. During an experience of twelve years in such an institution, he had never known of a single case, and of only three instances in which the matter of the patient's insanity was disputed. The popular impression is, therefore, altogether erroneous. In the public hospitals, particularly, the physicians in charge are much more anxious to get rid of patients than to keep them. As to the treatment received in these institutions, he thought it would be more successful if they were not obliged to take such a large number of patients. The plan of sending certain classes out among farmers, as is done in Belgium, might, perhaps, be of advantage here. Then, again, in the asylums there is often injudicious interference on the part of the friends of inmates just at critical times, when it does great injury.

DR. MACGREGOR mentioned certain peculiarities about the community of Gheel, in Belgium, which, it seemed to him, would militate against the success of adopting the plan here; but still, he thought the experiment one worth trying.

DR. IRA B. READ read a paper on

DOUBLE POPLITEAL ANEURISM.

The case upon which it was based was one in which the aneurism in one leg developed after the other had been successfully treated by ligation of the femoral artery, after various other expedients had been fruitlessly tried. Ligation of the femoral was performed in this instance also, and both tumors have entirely disappeared. From his experience he would lay down the rule, never to be departed from, that, when compression can be made in the artery above the diseased portion, it should always be resorted to as a means of lessening the danger consequent upon ligation of the artery. In popliteal aneurism, if compression of the femoral is made, the blood, being shut off from the latter, gradually distends the profunda and other smaller branches, and if, in the meantime, the surgeon can induce the formation of a clot within the aneurismal sac, so much the better. But, in case it is necessary to ligate the femoral, heat and nourishment, and sensation will thus be successfully maintained in the lower part of the limb, and the danger of gangrene avoided.

DR. J. W. S. GOULEY presented a number of specimens of

PAPILLOMA OF THE BLADDER.

The first was from a patient seventy-four years of age. There were no symptoms connected with the urinary apparatus until within a year or two of his death, when he was seized with a free hemorrhage from the bladder. Hemorrhage afterward recurred at irregular intervals, but always ceased spontaneously. At last he had a very violent attack during which he lost a quart of blood. In the bladder, which was exhibited, were found two villous growths with hard bases; while the vascular portions could be seen floating in the alcohol in which the specimen was preserved. Dr. Gouley said that when he first examined the tumors he thought that the bases were of a sarcomatous nature, and it was possible that this might be the case. The points of significance about this, as well as the other cases to be noticed were, that the hemorrhage was never constant, and that it was checked spontaneously.

The second case was that of a German, forty-five years of age, who was admitted to Bellevue Hospital, October 26, 1878. He had had cystitis twelve years before this, but the first attack of hemorrhage of the bladder came on just one year before admission. From that time on the hemorrhage was repeated irregularly, both as to quantity and frequency of occurrence. He died of pleurisy in January, 1879, and at the autopsy empyema was found. There was a slight deposit of tubercles at the apex of the right lung, and a gangrenous infarction in the lower lobe of the left lung; while in the upper lobe of the latter there was a cancerous formation. In the kidneys there was an advanced stage of pyonephritis with cystic degeneration. The ureters were both considerably dilated, and, in the bladder, which was markedly hypertrophied, three papillomatous growths were found. The bladder, ureters, and kidneys were exhibited.

In the third case the patient was about fifty years old, and had been under Dr. Gouley's care for about nine years, when he had his first attack of hematuria. The hemorrhage afterward recurred at irregular intervals, five or six months sometimes intervening between the attacks. Later the hemorrhages became more frequent. Bilateral cystotomy was performed, and a number of papillomatous masses were torn away with the forceps. The patient was relieved, but died at the end of three months from exhaustion and probably advanced renal disease. If another similar case should present itself, he said, he would operate simply to afford temporary relief.

The fourth case came under Dr. Gouley's care about a year ago, with the same history as the others. The diagnosis of papilloma was made in this, as in the preceding case, by removing a small portion of the growth through the urethra and placing it under the microscope, when the characteristic vascular structure was at once manifest.

The fifth case was that of a young physician whom he first saw about six months ago. As in the other instances, the diagnosis was made by removing a piece of the growth with a pair of small forceps; but the patient had as yet declined to submit to an operation. There had now been no hemorrhage for a considerable interval, but he felt confident that it would inevitably recur in time.

In the sixth case a small portion of the tumor came away in the eye of a catheter inserted into the bladder; so that he was enabled to make the diagnosis at once. The patient had had hemorrhages from the bladder at irregular intervals for two years, and when first seen, he had the appearance of a person suffering from advanced renal disease. Bilateral cystotomy was performed, and Dr. Leale was present at the operation. A complete evulsion of the tumor was made, the entire mass being removed in pieces, and the operation lasting about three-quarters of an hour. Fifty-four hours afterward, however, the patient died of uræmia.

In regard to the diagnosis of these tumors, it is worth while in all cases to pass into the bladder an instrument by which a small portion of the growth can be removed, and if this cannot be accomplished, to make an exploratory cystotomy and insert the finger into the bladder. The question naturally arises whether these growths are malignant or not. It was formerly supposed that they were, but there seems to be no good reason for such an opinion, as a rule, though in special cases there may be a carcinomatous element. Such tumors are not very common, but it is probable that they occur more frequently than is generally supposed. As to the evulsion, probably the safest instrument for this procedure is that devised by Mr. Reginald Harrison, of Liverpool, in the use of which it is easy to avoid grasping other tissues than the growth to be removed.

DR. JOSEPH D. BRYANT inquired as to the cause of the hypertrophy of the bladder in the second specimen exhibited.

DR. GOULEY said that whenever there is a foreign body, or a growth such as had existed in this case, in the bladder, concentric hypertrophy and contracture are apt to result, as time goes on, from the continuous efforts of the organ to get rid of its contents by contraction. In the first case the patient did not live long enough to have this concentric hypertrophy develop. In regard to the cause of these papillomata, he would say that he believed that in each case there is some previous lesion which gives rise to the condition. This may be but a slight abrasion of the mucous membrane, caused, for instance, by a small calculus, which afterward passes away, but the granulations resulting from such an abrasion will be sufficient to afford a starting-point for the villous growths. As to the intermittent character of the hemorrhage, this is probably to be explained by the fact that the denudation of the membrane covering the growths, which gave rise to the hemorrhage, was followed by an inflammatory process which blocked up the vessels, and thus prevented a further escape of blood.

DR. J. P. OBERNDORFER inquired whether he had in the diagnosis of these tumors made use of rectal examination, by introducing half the hand into the rectum.

DR. GOULEY replied that he had not, as he did not consider this procedure justifiable under ordinary circumstances, on account of the risk involved in it. Besides, it would be impossible to feel, through the thickened walls of the bladder, a soft growth of the character under consideration. A hard growth might be detected from the rectum, and in young subjects, where the prostate is so small, he is accustomed to practise digital exploration.

DR. T. J. HEARNEY said that he had at present under observation a case in which the symptoms resembled those described by Dr. Gouley. He doubted whether the operation would be followed by good results in patients accustomed to high-living, in whom there is a tendency to Bright's disease, on account of the danger of exciting an inflammatory process which would spread to the ureters and kidneys.

DR. BRYANT said that he had recently seen, in consultation, a case outside the State which he had every reason to believe was of the kind described by Dr. Gouley. At the time of his visit the patient was much prostrated; but he had advised perineal section as soon as his condition would warrant the operation. He would like to ask Dr. Gouley if there are not some definite symptoms which will enable us to make a diagnosis of papilloma of the bladder, as he thought it is now somewhat difficult to detect the condition. How is it to be distinguished from other affections of the bladder, such as stone, for instance?

DR. GOULEY expressed the opinion that a series of symptoms could undoubtedly be formulated which would be of sufficient diagnostic value. If there is a stone present, there may or may not be hemorrhage. It is, however, very infrequent in young subjects; and, therefore, when hemorrhage from the bladder occurs in a patient under forty, without any assignable cause, it is reasonable to suspect something of this sort. The peculiarity of hemorrhage resulting from papilloma, as he had previously pointed out, is that it comes on at irregular intervals, and stops spontaneously. Furthermore, as time goes on, the attacks increase in frequency and severity, and later there is cystitis; while the frequent contraction of the bladder in its efforts to expel this sponge-like growth gives rise to concentric hypertrophy of its walls. But he had brought forward something better than symptoms, viz., a crucial test of the condition. It is the duty of the surgeon to pass an instrument through the urethra, and with it remove a small piece of the tumor, and in this way he had now made the positive diagnosis of papilloma in four cases. There was nothing new in this procedure, however, as Civiale had done the same thing fifty years ago. When there is any doubt about the diagnosis, the exploratory operation through the perineum appeared to him perfectly justifiable.

THE PRESIDENT stated that, in justice to Dr. Gouley, it was his duty to say that in the case where Dr. Gouley mentioned that he had been present, a diagnosis of papilloma of the bladder had been as strongly asserted as was possible, and that Dr. Gouley arrived at his conclusions in this instance after a thorough examination of a minute portion removed at one of this previous exploratory examinations, and which consisted of a portion of the tuft from the cystic growth.

After a beautifully performed median cystotomy, he had, by invitation of Dr. Gouley, made a digital examination of the bladder through the perineal wound, and distinctly felt the papilloma, as it was situated at the right of the fundus of the bladder, and which at a subsequent operation was found to have been entirely removed by Dr. Gouley. The principal point of interest was the accuracy of the diagnosis.

DR. T. R. VARICK, of Jersey City, presented, by invitation,

A VESICAL CALCULUS OF UNUSUAL SIZE,

which he said he had removed from a lad fourteen years of age, on the 9th of December, by the bilateral operation. This stone weighed four ounces and four scruples, Troy weight, and was six and three-quarters inches in circumference in its longitudinal direction, and five and a half inches in its transverse. He had had it sawed open, and the section showed a nucleus of uric acid, surrounded successively by layers of urate of ammonia, triple phosphates, and urate of ammonia again. It had been six years since the first symptoms of bladder trouble were noted.

In operating, he had commenced with the left lateral incision; but, finding that this was insufficient, he had made a right lateral incision also, so that the external wound was somewhat of a V-shape. On account of the large size of the stone, he had found great difficulty in extracting it, and had, in fact, to follow the curve of the pelvis, and deliver it very much as if it had been a fœtal head. There was considerable shock from the operation, but the patient rallied speedily, and up to the present time (the twelfth day) he had progressed without an unfavorable symptom. On three days the temperature had gone up to 101°, but at all other times it had been entirely normal, The urine had been found to contain a large amount of mucus, some pus, and a small amount of albumen.

According to Sir Henry Thompson, the rule is, that in all cases where the stone weighs more than three ounces, the high, or suprapubic, operation is to be adopted; but in this case, on account of the elasticity of the soft parts, and the small size of the prostate, from the boy's age, he had decided to disregard this. After the operation he had applied hot water to the raw surfaces, and the wound was healing rapidly—in fact, too rapidly—since, on account of the condition of the bladder, he thought it better that the urine should find exit through the perineum for some time. The boy is certainly doing perfectly well up to the present, but whether there would be any resulting disease in the kidneys or not, he could not say.

DR. GOULEY said that this case affords a beautiful illustration of the extent to which young subjects will bear bladder irritation. He thought that the boy would get well, and that he would not have any pyonephritis. If the patient had been an old man, there would, undoubtedly, have been a fatal termination in a case like this, as there would have resulted disease of the ureters, followed by that of the kidneys. The good result here was due to the practical absence of the prostate. Personally, he said, he would not have dared to extract such a stone as this entire, but would, by all means, have broken it up into four or five pieces. There are instruments now capable of doing this, and if it cannot be accomplished otherwise, it may first be perforated in several places. This is a much safer procedure, and Malgaigne had called it "lithotriptric lithotomy." Dr. Gouley had given it the name of "lithoclastic lithotomy," which, he thought, is better.

He was glad that Dr. Varick had refused to perform the suprapubic operation, and he said that he would take this opportunity to offer his protest against this procedure. The high operation is a dangerous one, the mortality from it being very great; and, among the complications which are to be feared in connection with it, are the protrusion of the intestine from the wound, and infiltration of urine. It may be the present fashion, but it is one which will pass away, as it has already done three times before.

THE CHICAGO GYNECOLOGICAL SOCIETY.

Stated Meeting, November 17, 1885.

THE PRESIDENT, DANIEL T. NELSON, M.D., IN THE CHAIR.

DR. JOHN BARTLETT read a paper entitled

REMARKS ON THE TOXIC PROPERTIES OF SASSAFRAS.

He stated that, for some years past, he had had an intention of bringing before the profession reasons, rather feeble it must be admitted, for the supposition that the medicine under consideration has marked potency in a direction, so far as he knows, not suspected by medical men. Up to this time the declaration on the

part of standard writers that sassafras is a remedy of questionable power, and the fact that it is hawked about the streets and used freely as a tea all over the country, have caused him to refrain from bringing before a scientific body his limited experience presently to be detailed. But the recent declaration that this drug possesses toxic properties may justify him in making the following statement:

Years ago, he was called to a woman among the poorer classes, of good intelligence and education, who was having a miscarriage. Upon inquiring as to the cause of the mishap, with a prefatory reference to her poverty and already large family, she stated that she had induced the abortion herself—that she had done so on previous occasions. She had employed, she said, "what other women used," sassafras tea. She was surprised that he did not know of the property of sassafras as an oxytoxic. She spoke as if all her friends knew how to use it as an ecbolic, and she evidently looked upon it as a specific. Tea, she said, made from four or five pieces of the root, as large as the thumb and twice as long, would produce abortive effect.

A year or two later, he was called to a woman two months pregnant. For several days she had had symptoms of miscarriage of so pronounced a character that arrest of the process was doubtful. He found the patient very anxious to have a child; she disclaimed the intention of inducing abortion, and to all inquiries as to a possible cause of the hemorrhage, she gave answers which left him no further question except this: "Have you been drinking sassafras tea?" Surprised, she replied that for a week past she had used it at breakfast and supper. The proper remedies for her condition were prescribed, the possibly offending tea left off, and in twenty-four hours all was quiet *in utero*.

Further than this, his experience with sassafras as a possible abortifacient does not extend.

A study of the toxic effects of sassafras as reported by Dr. Hill, and here suggested, would seem to show a resemblance to three familiar articles, opium, strychnine, and ergot. In its action as a narcotic and sudorific, it resembles opium. In its property of inducing tetanic and clonic spasms, followed by paralysis, it is similar to strychnine. In its alleged power of exciting the uterus, it may be likened to ergot.

It may be of interest to call attention to the fact that the first reference to the use of ergot as an ecbolic was made by Stearns, in 1807, whereas it had been used by midwives certainly as early as 1688, and probably very much earlier.

DR. JAMES H. ETHERIDGE referred to the action of the oil of sassafras on the motor centres in the spinal cord supplying the uterus.

DR. EDWARD WARREN SAWYER said that in New England sassafras is a popular emmenagogue. Mothers are in the habit of giving decoctions of sassafras and tansy to their daughters in case of delayed or suppressed menstruation. Many of the essential oils produce the effects ascribed to sassafras by Dr. Bartlett. In the South, oil of sassafras is a popular remedy for uterine disease.

THE PRESIDENT inquired as to the chemical constitution of the volatile oils?

DR. H. P. MERRIMAN replied that many of the volatile oils are identical in chemical relations, but differ in physical properties. Such oils are *isomerides*. The essential oil of lemons, of bergamot, neroli, lavender, pepper, camomile, caraway, clover, etc., are isomerides of the oil of turpentine. Oil of turpentine is a hydrocarbon, possessing the formula $C_{10}H_{16}$.

DR. H. T. BYFORD was of the opinion that the oil of sassafras exerts its influence locally upon the alimentary canal and pelvic viscera, rather than upon the uterine nervous centres, as in the case of ergot. This would account for its popularity as an emmenagogue, mentioned by Dr. Sawyer. He had recently given one drop, combined with one-half grain of piperin, every three hours, for two weeks, in a case of typhoid diarrhœa. Slight strangury, disappearing with the discontinuance of the drug, was produced.

DR. CHARLES WARRINGTON EARLE presented, for Dr. Joseph Haven,

A TERATOMA,

corresponding in development to the third month, and bearing an asserted resemblance to a pup.

Dr. Haven had attended the family of Mrs. H. for the past four years. During this time he had had occasion to notice that the younger daughter was a person unusually strong in her likes and dislikes, of a nervous temperament, slight build, yet a sensible, educated, and attractive girl. On the 8th of September, 1885, this young lady, in company with her sister, called at his office to consult him with reference to her condition. He made the following entry in his case-book, as the result of her visit:

"Mrs. D., nineteen years old, married one and one-half years, always regular as to her courses up to July 21st; since then no show. Physical signs point to pregnancy in the sixth week." A few days later he saw her again. She was nervous and highly excited—almost hysterical. She told him, in an excited manner, that a dog had jumped on her, and that she "hated dogs." She complained of pain in the abdomen, low down. From that day until the 1st of November Dr. Haven saw her several times. Each time she was threatened with miscarriage, and each time she declared she was positive she could never carry that child. Her husband and sister told him that, asleep or awake, her mind seemed to dwell continually upon that dog; that she daily wondered if the child would be marked. Mr. D. said that ever since he had known her she has been afraid of dogs; she would always cross the street rather than meet one, and he has often jokingly refused to take her out with him, telling her, as an excuse, that they might see a dog, and she would make a scene.

On the night of November 1st, the husband roused Dr. Haven, desiring him to go over and see his wife, thinking it to be only a repetition of former attacks. An examination proved that Mrs. D. was about to lose the contents of the uterus. She was flowing constantly. The os had dilated slightly, and Dr. Haven could just reach the presenting part. The history of the miscarriage was the usual one, and the result was seen in the specimen presented. She insisted on seeing the fœtus, and declared it to be the image of the dog that had frightened her.

A general discussion upon the subject of maternal impressions followed.

Dr. Charles Warrington Earle presented specimens from

A CASE OF ARTIFICIAL ABORTION.

The fœtus corresponded in development to the fourth month of pregnancy, and was not decomposed. It was closely enveloped in the membranes, and entire absence of the liquor amnii was noticed. Hemorrhage into the placenta and decidua was not observed.

Mrs. F., American, has given birth to five children, the youngest twenty months old; labors always normal; has a history of anæmia for some months', if not years', standing; last menstruation ended May 20, 1885; in June, had a very slight discharge of blood; during the weeks following she would occasionally lose a small amount of blood: at other times there would be profuse hemorrhage, lasting twenty-four hours. She had at one time a white, sticky discharge, something like the albumen of an egg. October 1st, began to flow constantly, with some pain in back and sides, particularly the left. Was seen by Dr. St. John October 12th, at which time he exhibited the usual styptics with rest. She continued to flow, with pain, for another week, when hemorrhage was so severe, and prostration so pronounced, and with the suspicion of placenta prævia, it was decided that temporizing means should cease. After consulting with Dr. Earle, it was decided to induce labor. A catheter was introduced, and allowed to remain twenty-four hours, when pains came on, and the patient was delivered October 17, 1885. During the entire period of gestation the woman could not detect the usual signs of her former pregnancies. She made a good recovery, and menstruated November 20th, There had been no discharge of water perceptible to the patient during the entire period of pregnancy.

Dr. W. W. Jaggard thought Dr. Earle's case was a typical example of the condition technically termed *mummification*. The fœtus dies, and the fluid constituents of its body and envelopes are gradually resorbed. Mummification is usually observed in connection with twin pregnancies. One child is usually perfectly developed, while the other is converted into a mummy-like object. *Maceration* and *mummification* of the fœtus are observed when the membranes are intact; *putrefaction*, after rupture and entrance of air into the uterine cavity. Dr. Earle's case was, probably, not an example of that rare condition, abnormally small amount of amniotic fluid. There were no abnormal amniotic foldings, nor were the fœto-amniotic bands described by Simonart present.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, December 22, 1885.

The President Charles McBurney, M.D., in the Chair.

Dr. L. S. Pilcher read a paper on

ARTERIAL LIGATION AS A PROPHYLACTIC MEASURE AFTER SUDDEN, COMPLETE, AND PERMANENT OCCLUSION OF THE CHIEF VEIN AT THE ROOT OF AN EXTREMITY.

This subject depends for its interest and importance on these two questions:

1. When the chief vein of an extremity has been suddenly, completely, and permanently occluded at its root, are the collateral venous blood-paths always sufficiently ample to admit such a flow of blood through them that permanent circulatory and nutritive disturbances will not supervene? and

2. If in any appreciable proportion of cases, permanent circulatory and nutritive disturbances are likely to supervene upon such venous occlusion, what prophylactic effect, if any, would be exerted by the diminution of the force and volume of the arterial blood supply of the limb?

Each of the modifying conditions which have been specified in connection with the occlusion of the vein, are of importance. It must be sudden, for the tendency of the collateral venous branchlets readily and rapidly to enlarge *pari passu* with any encroachment upon a main venous channel, is such, that if the encroachment is gradual in its progress, by the time it has become complete, a very considerable enlargement of the collateral blood-paths will have been accomplished, with a corresponding diminution of any danger of circulatory embarrassment as a consequence.

In the consideration, therefore, of any clinical observations which may seem to have a bearing upon the questions raised, those cases cannot be considered as having much weight, in which a preëxisting tumor has for some time pressed upon, or possibly enveloped the vessel previous to its final complete and permanent occlusion.

The occlusion must be complete in order to supply the conditions requisite to produce sufficient embarrassment to the return circulation to awaken solicitude as to its ultimate consequences, while upon the permanence of the occlusion will depend the importance of an early resort to any measure that may possibly be prophylactic against consequent disability, the permanence of which could alone make their prevention a matter of anxious care.

After this preface, he took up the first question suggested: *Are the collateral venous blood-paths always sufficiently ample to admit such a flow of blood through them, in case the chief vein of the extremity has been suddenly, completely, and permanently occluded, that serious permanent circulatory and nutritive disturbances will not supervene?*

As bearing upon the reply to this, he called attention to certain anatomical considerations.

Sappey[1] states that "copious collateral communications exist between the large vein-trunks of the neck and at the root of the upper limb; channels always open, always adequate, and instantly responsive to calls upon them." He also adds: "If one of the great veins at the root of the neck is opened, the surgeon may ligate it without fear of interrupting the current of the blood."

This opinion, however, seems to be based upon a very limited number of experiments. If it were absolutely correct, there would be no occasion to include further the upper extremity in the consideration of the question proposed.

As to the lower extremity also, the statement has been made by Nicaise,[2] who based his statement, however,

[1] Sappey: Traité d'Anat. Descript., 1869, t. ii. p. 694.

[2] Nicaise: Des Plaies et de la Ligature des Veines, Thèse, 1872, p. 113.

on a single experiment in addition to previous experiments by Sappey, that, "after ligature of the femoral vein at the root of the limb, the return circulation is abundantly assured; although at the same time these experiments also show," he says, "that the anastomotic communications between the lower limbs and the trunk are less free than those of the upper limbs." With this conclusion, similar experiments by Richet[1] and Verneuil[2] coincide. Braune[3] (Leipzig), however, has claimed as the result of anatomical, experimental, and literary investigations, that usually the femoral vein has no collateral branches to conduct blood from the lower extremity to the abdominal cavity in case of its occlusion. In his experiments he failed, with an injection pressure of 20 mm. of mercury, to drive fluid from the peripheral branches of the femoral vein into the pelvic veins after ligation of the main trunk, in normal young subjects. He was more successful, however, on increasing the pressure.

The more recent and numerous experiments of Braun,[4] of Heidelberg, give more exact and reliable data on this question of the blood-paths collateral to the femoral vein. Forty experiments were made by this observer to test the readiness of the flow of fluids from the peripheral veins of the lower limbs into those of the pelvis, after ligature of the femoral at Poupart's ligament. In one, the injection passed into the pelvic veins with the greatest readiness, at a scarcely appreciable pressure, equalling at the most not more than 10 mm. of mercury thus demonstrating already existing collateral venous passages quite adequate to perform the function of the femoral vein itself. This was readily explained by the fact that there was present in this cadaver on the side operated upon, a long-existing glandular inguinal tumor, the gradually increasing intermittent pressure of which upon the femoral vein had occasioned a dilatation of the collateral branches. In seven others, a slightly higher pressure, ranging from 10 to 20 mm. of mercury, sufficed to drive considerable fluid into the pelvic veins, the obturator and ischiatic veins being the most common channels, but in some cases the median sacral, the circumflex iliac and the lumbar veins shared in the current. In eight other instances, a pressure of from 50 to 70 mm. was needed. In still other eight, from 70 to 120 mm. were required. In yet another group of eight, the pressure had to be raised to heights ranging from 120 to 150 mm. before success was secured. Of the remaining eight, in two cases a still further increase of pressure to from 150 to 170 mm. finally caused the injection to penetrate, but in the other six, occurring in four different individuals, absolutely no communication between the femoral vein and the pelvic veins could be established, notwithstanding a pressure of 200, and in some cases 300 mm. was kept up for an hour.

A review of these results by Braun, shows that in one-fifth of the total number of experiments, an injection pressure, not exceeding the normal pressure of the capillary blood-current (20 mm. Von Kries), sufficed to return fluid with considerable freedom into the veins of the trunk, notwithstanding the occlusion of the femoral. In these cases it may be accepted that no circulatory disturbances would have been manifested had sudden occlusion of the vein taken place during life. In the next one-fifth, in which a pressure double and treble the normal capillary was required, it may reasonably be allowed that in the living subject this extra force would have been so far supplied by the natural accessories to the venous current, muscular pressure, aspiration, and, possibly, gravity, that any marked or prolonged venous engorgement or capillary embarrassment would have been escaped, as in the first group of cases.

In the third and fourth groups, however, being two-fifths of the whole number, the high pressure required was such as would certainly have entailed marked circulatory disturbances in case of sudden occlusion of the vein during life. In the last group of cases, being likewise one-fifth of the entire number, in the two instances in which any permeability was secured, it was only by a force in excess of the maximum normal arterial pressure in man (150 mm.), while in the greater number a very much higher pressure failed absolutely. In these cases there was no possibility of the return of blood from the limb through any preëxisting collateral channels. Gangrene of the limb would have been inevitable, unless in some way the amount of blood pouring into the limb could be diminished, during the gradual opening up of new channels.

A similar careful and sufficiently extended series of experiments upon the axillary and subclavian veins is very desirable. The few experiments which have been above referred to, as made by different French observers, are by no means sufficient in number to warrant any general conclusion.

Dr. Pilcher then presented certain clinical considerations, with regard to the effects upon the circulation and nutrition of the arm which have followed sudden occlusion of the axillary vein higher up, or of the subclavian. He had not attempted to compile any statistics, nor did he know of any attempt to collate the results, so far as the after-nutrition of the arm is concerned, in any very large number of instances out of the many in which ligature of the axillary vein has been done in the course of operations for extirpating tumors from the axilla. In by far the great majority of such cases, it must be that no serious circulatory embarrassment has been experienced, a freedom that would naturally have been expected in view of the usually abundant collateral channels. But that complicating conditions may produce a different result, the following case in his own experience demonstrated, a case which first attracted his attention to the possible results of venous occlusion, and the question of how to obviate them.

Case I.—In January 1881, in the course of an operation for removal of carcinomatous axillary glands, being a recidive at the end of two years and nine months after the primary removal of the breast, it was necessary to sever the subscapular vein close to its entrance into the axillary; this was done, and the axillary vein itself was then tied by ligatures placed one above and one below the opening in its lateral wall thus made. The patient made a good recovery, and survived the

[4] Braun: Die Unterbindung der Schenkelvene am Poupartschen Bande., Archiv f. klin. Chirurg., Bd. xxviii. Heft 3, S. 610.

operation for five and a half years. Very shortly, however, after the vein ligature was done, an œdema of the forearm and lower part of the arm began to develop. This was accompanied with much aching, aggravated in moist and changeable states of the weather; the functional power of the limb, also, remained permanently impaired. This condition persisted without amendment during the remaining years of her life, and became much aggravated during the days of general prostration immediately preceding her death. In this case, in addition to the ligature of the axillary, there was simultaneous ligature of the subscapular branch as well, and also of other branches of less importance that were divided in the course of the process of clearing out the axilla. This must have diminished considerably the number of the collateral channels. But, practically, inasmuch as it is in just such cases that ligature of the main vein is most likely to be also required, this case is fairly illustrative of the conditions which require to be taken into consideration in connection with the occlusion of the main vein at the root of the upper extremity. It is obvious that, whatever may be the adequacy of the provisions for the collateral venous circulation, if simply the main trunk is occluded near its root, the case may be quite otherwise when more or less of the collateral branches have likewise become simultaneously occluded. In further illustration of this, he cited the following case:

Case II.—In April, 1885, he had occasion to remove an egg-sized carcinomatous glandular tumor at the root of the neck, in the right subclavian triangle. This was the proximal portion of a recurrent growth which likewise involved the glands of the axilla and the cicatrix left by the removal of the right breast for carcinoma two and one-half years previously. The excision of the cicatrix with the tissue adjacent that was infiltrated, and the cleaning of the axilla, were accomplished without accident other than the necessary severing of certain of the lesser veins of the axilla. The growth above the clavicle was next attacked. By the preliminary incisions for uncovering it, the external jugular vein, and the transversalis colli and suprascapular vessels were divided. The growth was deeply fixed behind the clavicle, and the infiltration of the circumglandular connective tissue was such as to negative easy enucleation, while traction was being made to lift it from its bed, after the outer portion had been freed, a sudden copious venous hemorrhage occurred from beneath and to the inner side of the growth. While this was controlled by properly directed pressure, the final removal of the tumor was accomplished. Examination now revealed that a rent had occurred in both the internal jugular and the subclavian veins, the inmost point of the growth having been embraced by these veins as they converge. Ligatures above and below the points torn were applied to each vein. He had now to deal with an occlusion not only of the internal jugular and of the subclavian within an inch of their junction, but also of the external jugular, and the transverse cervical and suprascapular veins, and of numerous smaller axillary branches. It was extremely improbable that the minute collateral communications that existed could enlarge with sufficient rapidity to return any considerable proportion of the blood which was being driven into the extremity through the axillary artery; already the limb was becoming blue and swollen, and the veins which were exposed in the axillary and cervical wounds were turgid with blood, as if under great pressure. The immediate danger was evidently from the continuous forcible distention of the extremity with arterial blood. To meet this supreme indication, he at once placed a ligature on the axillary artery in its upper part. The limb was then bandaged with a roller bandage, and proper dressings were applied at the seat of operation. The after-history of the operation wounds was uneventful. Union by first intention throughout the very extensive wound-tract, was secured, except at two points in the neck, where slight suppuration took place about some of the ligatures.

Twenty-four hours after the operation, the patient had experienced no pain in the head or elsewhere. The face was somewhat flushed, especially on the side of the ligated internal jugular. There was no swelling nor lividity of the fingers of the hand of the operated extremity, which was normally warm. The patient said, however, that the hand felt as if its veins were full.

During the second week a considerable œdema of the forearm manifested itself; bandaging and rubbing were employed to dissipate it, but it persisted without much change for about three weeks. It then rapidly diminished, so that at the end of eight weeks it had entirely disappeared. Meanwhile, the arm had regained much of its functional power, so that the patient was able to perform ordinary domestic work. Since this time her general strength and well-being have continued to improve. The arm is well-nourished, and though there is no apparent œdema, it seems somewhat more plump than its fellow. The radial pulse is still imperceptible. There are as yet no signs of recurrence of cancerous disease.

Such a case as this illustrates the statement that the question as to the adequacy of collateral channels when the main vein at the root of an extremity is suddenly occluded, as it is likely to confront the surgeon, may be a different one from the simple experiment of the anatomist when the latter isolates and ligates the axillary or subclavian vein alone, and then proceeds to throw in his injection. The two clinical observations just detailed justify the surgeon in the apprehension that permanent circulatory and nutritive disturbances of a serious character may ensue, when in the course of operations in the axilla or at the root of the neck, in addition to the division of a considerable number of lesser collateral branches, the main vein is also completely occluded. In the second observation it is true that the operator did not delay for the full development of the circulatory and nutritive disturbances which he had reason to apprehend would follow the extensive vein ligations which had been done, but proceeded at once to employ the only resource in his power for the diminution of the force and quantity of the inflowing stream of blood. Reference to the after-history will show, however, a train of circumstances, even more instructive than would have been the occurrence of a general gangrene of the limb from venous strangulation. It is apparent that production of free collateral inlets for the arterial supply was more speedy than the development of the corresponding venous outlets, whence the œdema that showed itself during the second week, and its persistence for some weeks, until the

slowly enlarging venous channels had become adequate, when it fully and finally disappeared.

With regard to the effect upon the circulation and nutrition of the lower extremity produced by occlusion of the femoral vein at the root of the extremity, the researches of Braun[1] have placed at our disposal a sufficient number of clinical observations to admit of deductions of practical value.

Of the 37 cases which Braun has collated, there are 18 in which ligature of the femoral vein alone, at the level of Poupart's ligament, was practised. Of these, 13 cases occurred as the result of wounds inflicted in the course of operations for the removal of inguinal tumors.

In none of these tumor-extirpation cases did gangrene ensue. In six of them the circulatory disturbance was either very slight and transient, or was absent altogether. In five others, though there was at first considerable cyanosis of the limb, it soon disappeared, leaving the limb entirely normal, or with but slight œdema. Two cases are recorded simply as having ended fatally, one by pyæmia, the other by inanition, without statement as to circulatory disturbances. Four deaths occurred among the other cases also from such causes as secondary hemorrhage, pyæmia, and pulmonary œdema.

These results corroborate the statements made in the earlier part of this paper as to the effect upon the development of collateral venous channels exerted by the pressure of a tumor in the groin upon the main trunk. The difference in this respect between an inguinal tumor and an axillary tumor is manifest. In the latter, the loose tissues of the axilla, and the position of the tumor on a plane below that of the vein, favor the considerable development of the growth without subjecting the axillary vein to pressure. Not so in the groin, where the denser tissues, the force of gravity, and the alternating states of tension and relaxation occurring in the flexion and extension of the thigh will very early cause a tumor to interfere with the free passage of blood through the underlying vein.

Five cases remain in which, as the result of acute injuries, high ligation[2] of the femoral vein alone was done.

The difference between the results precipitated in these acute cases and those in which preëxisting inguinal tumors had been present, is remarkable. In one only of the five was the recovery without disturbance. One died from septicæmia three days after the ligation, but without the appearance of gangrene; whether any less profound circulatory disturbance took place, or not, is not recorded. In one the limb became œdematous, with death by pyæmia; in the remaining two, fatal gangrene rapidly supervened.

[1] H. Braun: Die Unterbindung der Schenkelvene am Poupartschen Bande. Archiv f. klin. Chirurg., Bd. xxviii. Hft. 3, S. 610.

[2] I include in this class one case (that of Busch, 1870, being No. 32 of Braun's collection) in which the external iliac artery had been ligated forty days previously, and in which after that period of time, in the attempt to control a secondary hemorrhage, the femoral vein was wounded and tied. The reason for this, is that so long a time had elapsed since the primary arterial ligation, that a sufficient arterial collateral circulation had been established to restore the condition of the arterial supply of the limb to nearly its original fulness. The conditions were thus entirely different from those which would have been present had simultaneous ligation of the vessels been done originally.

In addition to these cases, he related a new observation, communicated by Dr. Wm. Browning, of Brooklyn, since it is closely allied to this class of acute cases.

Case III.—In 1881, in the course of an operation for the extirpation of a suppurating bubo, in a young man of about twenty years of age, the internal saphenous vein was wounded, and for the control of the hemorrhage a ligature was placed upon it close to the main femoral trunk. The patient recovered without special untoward symptoms, until he began to be up, when an œdema of the leg developed, which after long continuance in the upright position would become so great as to distend the whole limb up to the hip. During the night the swelling would largely disappear. At the expiration of about six months, when last seen, the tendency to œdema was still so great that he was unfitted for any work, and he begged for the removal of the limb.

Whatever the character of the obstruction to the venous return may have been in this case, it was sufficient to demonstrate positively the insufficiency of the collateral channels at the root of the limb.

The considerations, anatomical and clinical, which have now been presented, seem to me to be sufficient to justify the surgeon in the apprehension of serious circulatory and nutritive disturbances after sudden and complete occlusion of the root vein of an extremity; of the upper extremity, when the occlusion of the main vein is accompanied also by the simultaneous occlusion of any considerable number of the lesser and collateral venous channels; of the lower extremity, when the occlusion is sudden, and has not been preceded by any conditions which might have occasioned a preliminary enlargement of collateral channels, or the development of new ones.

Dr. Pilcher then proceeded to the consideration of the second question propounded, viz., *What prophylactic effect, if any, would be exerted by the diminution of the force and volume of the arterial blood supply of the implicated limb?*

The celebrity of two cases where ligature of the femoral vein, consequent upon acute injury sustained, had been followed by speedy and fatal gangrene of the leg, and the wide diffusion of the account of a case in which an obstinately recurring hemorrhage from wounds of the femoral vein, and many collateral branches, had been at once controlled by ligature of the femoral artery, with uninterrupted recovery thereafter, have served to give the procedure of simultaneous arterial ligation a status as an authorized procedure in cases of wound of the femoral vein. The cases referred to are the well-known cases of Roux and Linhart, and of Langenbeck. Following this trend of surgical opinion, Lidell, in 1883, in his article on "Injuries of the Blood-vessels," in *The International Encyclopedia of Surgery*, vol. iii. p. 213, says: "When hemorrhage from the common femoral vein makes deligation of that vessel necessary in order to stop the bleeding, the common femoral artery should also be ligated in most cases, in order to equalize the circulation.

But Braun had already, in the article of which so much use has been made in this paper, protested against this procedure as one which appeared to him to be dangerous to the patient, and neither sufficiently

warranted by clinical experience, nor by anatomical investigation or experiment on the cadaver.

Fortunately, the industry of this observer has furnished to us both the results of extended experiments on the cadaver, and of a full compilation of recorded clinical experience. Thus it is possible for anyone to analyze and make the basis of his own conclusions.

Pursuing his own analysis of these cases, he takes up those in which arterial ligation has been performed, either as a remedy for wounds of the femoral vein or in consequence of a simultaneous arterial wound, and compares the results with those in which the vein alone was ligated.

Eleven cases are reported in which such arterial ligation was done for the relief of wounds inflicted in operations for the extirpation of inguinal tumors. In two of these the artery alone was tied; the first is the case of Langenbeck, already referred to, which proceeded to an uninterrupted cure; the second was one of Kuester's, where the wound in the vein had been temporarily secured by hæmostatic forceps; the removal of these after twenty-four hours having been followed by renewed bleeding, Kuester proceeded to tie the femoral artery. This stopped the bleeding, but was followed by a rapidly progressive fatal gangrene. Of the nine cases in which both the vein and the artery were ligated, there were five cases of gangrene, one only recovering after amputation. Of the four cases in which no gangrene appeared two died from pyæmia, and one from secondary hemorrhage, leaving but one perfect recovery out of the entire class. This is in marked contrast with the results obtained in the same class of cases from simple ligature of the vein, and abundantly justifies the opinion, that in this class of cases ligation of the common femoral artery is dangerous to the patient, and unwarranted by clinical experience.

When we turn to the class of acute injuries a somewhat different result is found. Here are seven cases; in two of these the artery alone was tied, one followed by fatal gangrene, the other, although escaping gangrene, succumbing to pyæmia. Of the five remaining cases two recovered with little or no circulatory disturbance, three developed gangrene of the limb, of which two died and one recovered after amputation. If we compare these with the cases of the same class in which simple ligation of the vein was done, and take the cases of gangrene alone into account, pyæmia being regarded as a preventable accident, it appears that where the vein alone was tied, two out of five developed gangrene; where the artery was tied, either alone or simultaneously with the vein, four out of seven developed gangrene. These numbers are not large enough to settle the question positively, but so far as they go they likewise discourage the practice of ligation of the common femoral artery as a prophylactic measure after wounds of the femoral vein high up, even in acute injuries.

The case of simultaneous ligation of the femoral artery and vein which the writer presented to this Society one year ago[1] lacks, in an important particular, the requisites necessary to enable him to use it for purposes of comparison with the cases under consideration. On account of the conditions under which the ligations were made, he determined at the time of the operation the exact relative location of the vein wound, but his belief has been that it was below the point of entrance of the internal saphenous. Such being the fact, the relation of the case, as regards the amplitude of collateral channels, is quite different from those in which a ligature is applied at the level of Poupart's ligament. Whether, also, the arterial ligature involved the common femoral or the superficial femoral must be a matter of doubt. This, however, is worthy of note in this connection, that during the first few weeks after this patient began to go about, a considerable œdema of the leg and thigh manifested itself. This entirely disappeared within a few weeks, and the man has ever since remained free from disability from the injury. The case, nevertheless, will be found to have an important bearing, as indicating a rational course of action to be pursued in the graver forms of the accident under consideration.

The extreme gravity of a wound of the femoral vein above the opening of the internal saphenous vein, in cases where there has been no preëxisting inguinal tumor, is seen in the fact that, of the twelve cases which have been analyzed, one-half developed gangrene, all with a fatal termination except in one case in which amputation was followed by recovery. This fatal gangrene is due to acute venous strangulation of the limb. The immediate question which confronts the surgeon, therefore, is, how to prevent this, or to determine its intensity until a sufficiently free return of the venous blood is in some way provided for. Simultaneous ligation of the accompanying main arterial trunk has been shown by experience to increase the rate of mortality. Why this should be so, it is not difficult to understand, for to diminish to an extreme degree the arterial supply to a part the nutrition of which is already seriously compromised by general venous stasis, would certainly tend to precipitate and aggravate the threatened necrosis.

Braun (*loc. cit.*) founds his chief objection to the arterial ligation, on the fact that it deprives the arrested venous current of the *vis a tergo* which a full arterial current, bounding into the vessels of the limb, could exert, and by means of which he believes that in some cases the chief collateral branches could be sufficiently distended to admit an immediate adequate collateral flow to take place through them. If this theory were correct, an increase rather than a diminution of the arterial pressure in a limb would be an object to be sought in cases of the kind under consideration.

The physiology of the establishment of new collateral ways is, however, of quite a different character. It is by the dilatation and development of many previously minute and insignificant vessels that the new ways are established. Indeed the experimental results of the anatomists referred to in the earlier part of this paper, show that penetration of injected matters from the veins of the lower limb into the pelvic veins after ligation of the femoral, is not accomplished by overcoming definite valve-barriers, and thus gaining access at once to wide paths, for if a thick and solidifiable injection material is used, no penetration is observed, but when a different liquid, like turpentine colored with vermilion (Sappey and Nicaise), is used, then it flows with facility, for it now obtains entrance into a multitude of minute branches from the trunk into

[1] Annals of Surgery, vol. i. p. 167, Feb. 1885.

which it is first thrown, and then by multitudes of inosculating venules, it is received and carried on until it is gathered together again in the larger veins that emerge within the pelvis, and finally convey it to the ascending vena cava. In the living subject, the same phenomena are witnessed in every congested area, where the rapid enlargement of previously minute and invisible vessels quickly supplies a part with a copious network of vessels now plainly discernible and capable of transmitting a greatly increased volume of blood. If the inundation of blood is more rapid and intense than can be provided for by this vascular dilatation, necrosis must take place, just as upon a larger scale it does in so large a proportion of the cases of sudden occlusion of the femoral vein at the level of Poupart's ligament.

In cases of the accident in question, the greater the arterial *vis a tergo*, the greater the danger of overwhelming and fatally blocking the somewhat inefficient collateral radicles; while, if ample collateral paths exist, it is unnecessary; where less immediately available collateral paths exist, it becomes an element of danger just in proportion to the absoluteness of their insufficiency.

The idea, therefore, of obtaining benefit, in any case, from the preservation of the full arterial pressure upon the circulation of a limb, the chief vein of which has become occluded at its root, need never be entertained by the surgeon.

Having disposed of this consideration, the way is more clear to arrive at a conclusion as to what course is most likely to prevent the choking of the limb with blood, while the nutrition of the limb is still sufficiently provided for.

In the case of the lower limb, he suggested as a rational resource, and the one least likely to entail new dangers, ligation of the superficial femoral artery. If this vessel be ligated, while the quantity of blood and the force of the current through the limb will be very materially diminished, the amount of blood supplied to the limb will still be quite sufficent to provide for its nutrition.

Ligation of the superficial femoral artery is worthy of trial as a prophylactic measure in any case where sudden complete occlusion of the femoral vein has occurred at the root of the extremity. It is a rational means of accomplishing the immediate indication for lessening the amount of blood sent into the limb. As an example in support of this practice, my own case can now be cited; in this case the occlusion of the vein was at such a height that considerable œdema showed itself, and persisted for some weeks after the patient began to walk about, although none had manifested itself while he was recumbent. The fortunate absence of serious disturbance of any kind in the limb during the early weeks after the ligature of the vein, and the comparatively speedy and definitive disappearance of the œdema, are fairly attributable to the slight disturbance in the equilibrium of the arterial inflow and the venous output which the ligature of the superficial femoral secured. It is hardly necessary to state that in those cases in which a simultaneous wound of the common femoral artery and vein has occurred, there is no choice of procedure but to ligate at the point of injury. In such cases it is especially important that the vein wound be closed, if possible, by a lateral suture or lateral clamp, so that complete occlusion of the vein may be avoided.

Recurring to the upper limb, since abundant experience has shown that the nutrition of that limb is not hazarded by a ligature applied to the axillary artery, ligation of that artery may unhesitatingly be performed as a prophylactic measure in cases in which diminution of the arterial supply to the limb seems desirable in consequence of extensive occlusion of the venous outlets at its root.

The final conclusions reached as the result of the foregoing discussion may finally be profitably stated in the following recapitulation:

1. Serious circulatory and nutritive disturbances are to be apprehended:

a. In the upper extremity, when, in addition to the occlusion of the main vein at its root, simultaneous occlusion of any considerable number of the lesser and collateral branches has also taken place.

b. In the lower extremity, when the occlusion of the main vein at its root is sudden and complete, and has not been preceded by any conditions which might have occasioned a previous dilatation of collateral channels or the development of new ones.

2. The accidents of excessive œdema, and of gangrene, when they occur, are due to the intense and active congestion of the limb through increments of arterial blood for which there is no adequate outlet.

3. The development of collateral paths is not effected by the breaking down of valve-barriers at the entrance of large collateral trunks, but by the dilatation of a multitude of minute branchlets. To effect this, an increased arterial *vis a tergo* is not required. Any increase in the normal blood pressure is attended with danger of overwhelming and fatally choking up the somewhat slowly enlarging collateral radicles.

4. The diminution of the amount of arterial blood which enters a limb of which the chief venous outlets have become occluded, to an amount not greatly in excess of that which can readily find an outlet from it through paths still remaining, is the first great indication to be fulfilled in the treatment.

5. Whatever method is adopted to restrain the flooding of a limb with arterial blood, it must still permit the entrance of a supply sufficient for the nutrition of the limb. For this reason, in the lower limb, ligation of the common femoral is to be avoided, especially in the light of the disastrous results of such ligations already recorded.

6. Ligation of the axillary artery in the upper extremity, and of the superficial femoral in the lower, are safe expedients, and to be adopted as prophylactic measures, whenever occlusion of the venous outlets of a limb is so great as to hazard the integrity of the limb by reason of the circulatory stasis produced.

DR. POST remarked that he had never seen a case of gangrene following ligature of the superficial femoral artery for circumscribed popliteal aneurism.

DR. SANDS felt sure that he had seen such a result in hospital practice, although he could not at that time instance a case.

DR. STIMSON remarked that when he collated statistics on ligation with catgut, he found twenty-eight or twenty-nine cases, and the only one in which gangrene followed was that of Dr. Sands, in which the common iliac was ligated.

DR. FLETCHER asked, what disturbance if any, had oc-

curred in the arm where it had been necessary to tie the axillary vein.

Dr. Weir had had one case in which ligation of this vein was required, but the answer did not help the reader of the paper at all, because the patient died of pyæmia.

In another case, the vessel was wounded and tied laterally. Thrombosis and embolic process occurred, which resulted in the destruction of the eye of the same side. In this case the patient recovered with no disturbance of the circulation in the arm.

It is interesting, perhaps, to refer to a case which occurred under the late Dr. Mason's charge, that of a stab wound high up in the thigh, by which there was a communication formed between the artery and vein, and for which he put the patient under ether, and kept up compression for eighteen hours, at the brim of the pelvis, sufficient to close both artery and vein, without doing damage to the limb, although it failed to cure the arterio-venous aneurism.

During the war he had a case of gunshot wound at the edge of the groin, in which it was found afterward that the missile had torn the vein across and occluded the artery; gangrene and death resulted.

Dr. C. K. Briddon referred to two cases of thrombosis of the iliac vein occurring in men. The cause was very obscure. The limbs in both cases were the seat of a solid œdema which did not pit at all. One case occurred ten years ago, and the limb is still larger than the other. The circumflex veins are enlarged, and can be seen pursuing a tortuous course beneath the skin. The œdema was not that commonly met with in ordinary obstruction of the veins, such as is seen with secondary growth of cancer of the axilla, but was a growth of the limb.

He had not seen gangrene follow occlusion of the artery for popliteal aneurism, and he had ligated the superficial femoral for this purpose in eighteen cases. In one of these cases, in the New York Hospital, Dr. Buck subsequently tied the deep femoral, the external iliac, and the common iliac, but gangrene did not occur in the limb.

Dr. Sands said that in Bellevue Hospital, some years ago, a man was admitted under the care of one of his colleagues with a wound of the femoral artery and vein. The bleeding was arrested, but gangrene set in and rapidly carried off the patient.

Dr. Pilcher, as bearing upon the possible effect in these nutritive disturbances which ligation of the artery might induce, narrated a case which occurred ten years ago, that of a young woman who had enlargement of one leg and thigh, similar to that described by Dr. Briddon. In that case it was evidently due to venous obstruction. He ligated the superficial femoral, and the immediate result was very great improvement. As she then passed from his observation, he was unacquainted with her later condition.

Dr. Briddon remarked that in the two cases which he had mentioned, he regarded the enlargement as a hypertrophy due to slowing of the blood stream or obstruction in the femoral vein.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

Thirteenth Annual Meeting, held at Washington, D. C., December 8, 9, 10, and 11, 1885.

(Specially reported for The Medical News.)

Friday, December 11th.—Fourth Day.

The Advisory Council, through Dr. Rohé, of Baltimore, reported that

THE NEXT ANNUAL MEETING

of the Association would be held in Toronto, Ontario, on the first Tuesday in October.

THE OFFICERS FOR THE ENSUING YEAR

were then elected, as follows:

President.—Dr. Henry P. Walcott, of Cambridge, Mass.

Vice-Presidents.—Dr. C. W. Covernton, of Canada; Dr. G. B. Thornton, of Memphis, Tenn.

Treasurer.—Dr. J. Berrien Lindsley, of Nashville, Tenn.

Executive Committee.—Dr. Pinckney Thompson, of Kentucky; Dr. Henry B. Baker, of Lansing, Mich.; Dr. Joseph Holt, of New Orleans; Dr. Charles Smart, U. S. A.; Dr. C. N. Hewitt, of Minnesota; and Dr. H. A. Johnson, of Chicago.

Secretary.—Dr. Irving Watson.

Dr. C. A. Lindsley, of Yale College, read a paper entitled

AN EPIDEMIC OF TYPHOID FEVER.

He stated that there were no new points involved, and that he merely wished to add to the literature on the subject cumulative evidence of the propagation of typhoid fever by means of water and sewer connections.

Dr. Thomas F. Wood, Secretary of the State Board of Health of North Carolina, presented a paper entitled

OBSERVATIONS ON THE CAPE FEAR RIVER WATER AS A SOURCE OF WATER SUPPLY.

He narrated the experience of a company formed to make artificial ice by the ammonia process. They used the water of the Cape Fear River, which was boiled and the steam condensed, and the condensed water used for making the ice. It was found that the ice had a decidedly greenish color, and an odor of tar and creasote, and that a core formed in the centres of the frozen cakes which was highly impregnated with these wood products, and this, in spite of every care being used to keep the water in the boiler as fresh as possible. An examination into the cause of this showed that the river water was impregnated, to a certain degree, with substances capable of yielding these products when they underwent a process of destructive distillation in the boiler. The trouble disappeared only when well water was used and the river water wholly abandoned.

Drs. Thomas F. Wood, of North Carolina; S. W. Abbott, of Massachusetts; and Smith Townshend, of Washington, D. C., were appointed a committee on the subject of

VACCINATION AND VACCINE VIRUS,

to report next year.

MISCELLANEOUS BUSINESS.

The EXECUTIVE COMMITTEE recommended that the Conference of State Boards of Health be invited to become a Section of the Association, and it was so ordered.

The constitution was amended so that the Executive Committee shall consist of six active members, three to be elected each year, by ballot, and to be ineligible for election to that committee again.

THE ADVISORY COUNCIL recommended that Congress be urged to appropriate the necessary funds to equip the War and Navy Departments with materials for researches by the medical corps into the causes of infectious diseases. It also endorsed Dr. Holt's resolutions for a Congressional Commission to investigate and report upon yellow fever in its breeding places.

A committee of three was appointed, with Dr. J. S. Billings as chairman, to prepare a form for weekly, monthly, and yearly mortality reports.

The subject of the disinfection of sewers was referred to the Committee on Disinfectants, which was continued until next year.

DR. J. HOWARD GAYLORD, of Baltimore, Chairman of the Special Committee on

DISINFECTION OF RAGS,

reported that it is an admitted fact that the importation of rags is a prolific cause of the spread of infectious diseases, and that ports of entry are the gateways for their introduction. Foreign disinfection was not to be relied upon, and the Committee proposed that a resolution should be passed by the Association that all health authorities having jurisdiction over matters connected with maritime systems of disinfection, should thoroughly destroy all germs before the rags are permitted to be distributed for manufacturing purposes.

The report was, after a prolonged discussion, recommitted for further investigation by the Committee during the coming year, and Dr. J. H. Raymond, of Brooklyn, and Dr. Joseph Holt, of New Orleans, were added to the Committee.

REPRESENTATIVE SWINBURNE, of New York, made a short address, in which he commended the work of the Association.

CAPT. HENRY LOMB also thanked the Association for the good will it had shown him, and for the honor of election as a life member.

THE PRESIDENT announced that Mr. Lomb had decided to offer four additional prizes of $100, $75, $50, and $25, for the best plans for houses to cost $600, $1000, and $1500.

DR. REEVES, the retiring President, in his closing speech, alluded to the good work which had been accomplished by the Association during its existence of thirteen years, and the Association then adjourned.

NEWS ITEMS.

AN ITALIAN TRANSLATION OF PEPPER'S SYSTEM OF MEDICINE is announced as in course of preparation.

PASTEUR'S INOCULATIONS.—On the 13th of December last, M. Pasteur inoculated in the presence of M. Gomot, the Minister of Agriculture, forty persons who had been bitten by dogs, with the attenuated virus of rabies.

SCHOOLS OF MEDICAL PRACTICE IN THE GOVERNMENTAL SERVICES.—Mr. Lowry, on Dec. 21, 1885, introduced in the House of Representatives the following joint resolution, relative to schools of medical practice in the United States, and to the graduates thereof:

Resolved by the Senate and House of Representatives of the United States of America in Congress assembled, That it shall be a misdemeanor, punishable by a fine of five hundred dollars and dismissal from office, for any officer of the United States Government, civil, military, or naval, to make discrimination in favor of or against any school of medical practice, or its legal diplomas, or its duly and legally graduated members, in the examination and appointment of candidates for medical service in any of the Departments of the Government.

SEC. 2. That all such examinations shall be open to the attendance and witness of all physicians, citizens of the United States; and that duly certified copies of the complete records of all the details of said examinations shall be placed on file in the office of the Librarian of Congress, subject to the inspection and use of members of Congress.

THE PROSPECTS OF THE DENTAL SECTION OF THE INTERNATIONAL MEDICAL CONGRESS.—*The Dental Cosmos*, for January, states that, "as an unbiassed recorder of facts, the *Dental Cosmos* is forced to the statement that, 'under existing circumstances,' the majority of the profession apparently deem it inexpedient to continue the effort for perfecting the organization of a Dental Section of the International Medical Congress. Such was the purport of a resolution adopted without a dissenting voice at an informal conference of some twenty leading dental practitioners at Buffalo, in November. At the recent anniversary of the First District Dental Society of New York, the opportunity afforded at an entertainment given to the guests from other cities was utilized by taking an informal vote on the question of 'expediency.' Out of about forty present, there were but two votes in favor of coöperation."

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK will hold its Eightieth Annual Meeting in the City Hall, Albany, on Tuesday, Wednesday, and Thursday, February 2, 3, and 4, 1886. The following papers have been promised:

Lessons in the Management of Clubfoot, by V. P. Gibney, M.D., of New York.

Methods of Diagnosis, by Lawson Tait, F.R.C.S., of Birmingham, Eng.

Vesical Calculi in Female Children, with cases, by N. A. Powell, M.D., of Edgar, Ont.

Rheumatic Affections of the Joints, by A. Hadden, M.D., of New York.

Notes of Autopsy disclosing Absence of the Liver, by Benj. C. Senton, M.D., of Whitehall.

Peritonitis of Infants and Children, by A. Jacobi, M.D., of New York.

The Free Dispensary System, by Joseph W. Howe, M.D., of New York.

Infant Feeding, by E. F. Brush, M.D., of Mount Vernon.

Consultations, by Lawrence Johnson, M.D., of New York.

Medical Testimony and the Hypothetical Question, by William C. Wey, M.D., of Elmira.

The Recording of Cases (1); The Effect of the Electric Light on the Eye (2), by Lucien Howe, M.D., of Buffalo.

The Establishment of a State Board of Medical Examiners, by P. R. Furbeck, M.D., of Gloversville.

Burns Considered as Wounds, and Treated According to Scientific, Antiseptic Methods, by Robert J. Morris, M.D., of New York.

Antiseptics in Midwifery, by Walter B. Chase, M.D., of Brooklyn.

The Results of the Operation for Convergent Squint, by D. B. St. John Roosa, M.D., of New York.

Spontaneous Expulsion of a large Calculus in the case of a Female aged Sixty-eight Years, by Harvey Jewett, M.D., of Canandaigua.

Leprosy in Japan, by D. B. Simmons, M.D., of Poughkeepsie.

The Clinical Diagnosis of Cancer sufficient for Practical Purposes, by Daniel Lewis, M.D., of New York.

Some Observations on the Treatment of Uterine Displacements in General Practice, by L. E. Felton, M.D., of Potsdam.

Obstetric Palpation, by W. W. Potter, M.D., of Buffalo.

Ovarian Tumor; Advantages of early Ovariotomy; Disadvantages of Delay, by T. H. Squire, M.D., of Elmira.

Megrim with Intermittent Ptosis, by J. C. Shaw, M.D., of Brooklyn.

Acute Nephritis, especially as following Diphtheria, by A. R. Simmons, M.D., of Utica.

Treatment of Aural Polypi by the Injection of Carbolic Acid, by Herman Bendell, M.D., of Albany.

Tinea Tonsurans; or Ringworm of the Scalp, by F. C. Curtis, M.D., of Albany.

A Clinical Note on Bright's Disease, and Diabetes Mellitus, by Wesley M. Carpenter, M.D., of New York.

Report of a Case of Empyema, by B. F. Sherman, M.D., of Ogdensburg.

On the Limitation of the Contagious Period of Syphilis, in Relation to Marriage, etc., by Fessenden N. Otis, M.D., of New York.

General Arterio-capillary Fibrosis; its Relation to Cardiac and Renal Disease, by Alfred L. Loomis, M.D., of New York.

Prevention of Hemiplegia, by W. H. Thomson, M.D., of New York.

A Case of Tumor of the Maxillary Antrum and Orbit, by T. R. Pooley, M.D., of New York.

The Early Management of Cases of Mental Depression, by Willis E. Ford, M.D., of Utica.

A Comparison of some of the Modern Methods of Treating Ununited Fractures, by Geo. R. Fowler, M.D., of Brooklyn.

Ulcerative Endocarditis, by H. R. Hopkins, M.D., of Buffalo.

Cholera, by J. A. S. Grant, Bey, M.D., of Cairo, Egypt.

Fatty Tumors of the Knee-joint, by R. F. Weir, M.D., of New York.

Treatment of Tertiary Syphilis of the Nose, Mouth, and Throat; Records of Cases presented and fully Illustrated, by D. H. Goodwillie, M.D., of New York.

Ozæna, by John A. Roe, M.D., of Rochester.

Hygiene of the Ear, based upon the Records of more than 2800 Cases, by C. R. Agnew, M.D., of New York.

History of a Case of Abscess of the Kidney, by C. L. Stiles, M.D., of Owego.

Remarks on Pelvic Inflammations in Females, and their Treatment, by A. M. Jacobus, M.D., of New York.

Diseases of the Fallopian Tubes; with Reports of Cases, and Characteristic Specimens, by W. Gill Wylie, M.D., of New York.

Report of a Case of Swallowing a Plate with four Artificial Teeth, the same being passed, per rectum, on the sixth day; with remarks, by L. M. Bates, M.D., of Canaan Four Corners.

Excision of the Knee-joint, with Cases, by A. M. Phelps, M.D., of Chateaugay.

Hemorrhage after Removal of the Cervix Uteri for Epithelioma, with the Galvanocautery Wire, by James P. Boyd, M.D., of Albany.

The Benefits arising from Laws regulating the Practice of Pharmacy, by A. B. Huested, M.D., of Albany.

Migraine, by Floyd S. Crego, M.D., of Buffalo.

Cremation, by Charles Cary, M.D., of Buffalo.

Tubercular Ulceration of the Pharynx, by F. W. Hinkel, M.D., of Buffalo.

Medical Honors.—The honor of knighthood has been conferred on Dr. Paget, of Cambridge, and Dr. William Roberts, of Manchester.

Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the Three Weeks ending January 2, 1886.

Purviance, George, *Surgeon*.—To proceed to Chicago, Illinois, as Inspector, December 23, 1885.

Guitéras, John, *Passed Assistant Surgeon*.—To proceed to Saint Louis, Missouri, for duty, December 23, 1885. Granted leave of absence for seven days, December 26, 1885.

Urquhart, F. M., *Passed Assistant Surgeon*.—To proceed to Charleston, South Carolina, for temporary duty, December 23, 1885.

Bratton, W. D., *Assistant Surgeon*.—Granted leave of absence for twenty-two days, December 22, 1885.

McIntosh, W. P., *Assistant Surgeon*.—Granted leave of absence for fourteen days, December 22, 1885.

Guitéras, John, *Passed Assistant Surgeon*.—Upon expiration of leave of absence to reassume charge of the Service at Charleston, South Carolina, December 29, 1885.

Fattic, J. B., *Assistant Surgeon*.—Appointed an assistant surgeon December 28, 1885; assigned to duty at Baltimore, Maryland, December 29, 1885.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department of the U. S. Army, from December 29, 1885, to January 2, 1886.

Maddox, Thomas J. C., *First Lieutenant and Assistant Surgeon*.—Killed December 19, 1885, in affair with Apache Indians near the White House, New Mexico.

ORIGINAL LECTURES.

PAINFUL MICTURITION IN INFANTS, AND NOCTURNAL INCONTINENCE OF URINE; CAUSES AND TREATMENT.

A Clinical Lecture, delivered at the Philadelphia Hospital.

BY JOHN M. KEATING, M.D.,

VISITING OBSTETRICIAN TO, AND LECTURER ON THE DISEASES OF WOMEN, ETC., AT THE PHILADELPHIA HOSPITAL.

(Reported by Harrison Gill, Student of Medicine.)

GENTLEMEN: I bring before you this morning this little boy, whose age is about two years. My attention was called to him the other evening during my visit to the ward. The resident physician, Dr. Peck, informed me that the child was restless, moaning or crying constantly; that it had been in this condition for the last twenty-four hours, and nothing seemed to give it relief. The child did not have loud, screaming attacks, as if it were in acute pain, but at the same time there was something annoying it which gave rise to the condition noticed. Now, let me tell you that the temperature was normal, that the bowels were regular; the lungs were normal, with the exception of very slight bronchitis, which is always more or less present at this time of year.

These symptoms will often present themselves to you, and it becomes a matter of great importance for you to make a diagnosis, in order to be effectual in your treatment. One of the first things that would strike you would be possibly earache; this is of very common occurrence in children, especially during these damp fall months or in the early spring. Some children are very liable to catch cold, to have sore throats, acute tonsillitis and pharyngitis, and when your attention is called to them you will notice redness of the mucous membrane, possibly upon the tonsils, the follicles of which become very much enlarged, with grayish patches in the valleys or depressions of the glands; there are usually present fever, malaise, loss of appetite. Now, this must not be confounded with diphtheria, which is a disease having symptoms very much more prominent as regards their constitutional character, and with the appearance of membrane—that is to say, grayish patches adherent to the mucous membrane of the half arches and soft palate, and very difficult to detach.

In these cases of acute follicular pharyngitis or tonsillitis, the inflammation is apt to extend through the Eustachian tubes and involve the structure of the inner ear, possibly attacking only one, possibly both, and giving rise to a series of symptoms which are most distressing to witness. The child will have a history of ear trouble possibly, or this may be overlooked, but there will be a constant fretfulness, sleeplessness, loss of appetite; the child will continually cry, probably have paroxysms of great pain, in which it will endeavor to bury its head in the pillow, or will throw itself from its nurse's arms in fear of being touched, or it will place its hand to the place affected, and in this way determine the seat of the lesion; if it is very young, you will have to make a diagnosis by exclusion, and possibly after applying warmth to both ears, giving the child an opiate to relieve its pain, a hot foot-bath as a derivative, you will be rewarded by the child's having a comfortable night's rest, and exhibiting the signs of the discharge from the ear affected upon the flannel or poultice which you placed over it the night before. The child before us gives no indication of aural trouble.

Having eliminated almost every source of trouble, we turn to the urinary organs as the solution of the problem. Retention of urine is very often overlooked in children, and sometimes gives distressing pain. The mother will tell you that the child has passed its water, having possibly left it to the nurse to attend to, and the nurse, in her turn, left it to the mother.

In this case, fearing some such cause, I passed a catheter, but found the bladder empty; but when doing so I noticed that the meatus urinarius was extremely inflamed, the mucous membrane was red and bulging and moist, and the prepuce very long, extremely contracted, and impossible to retract over the gland—in fact, it was adherent firmly to a great extent. The child seemed to suffer extremely as I made this examination, and I felt sure that we had detected the cause of the difficulty. It was placed in a warm hip-bath, was given alkalies freely, large doses of bromide with some chloral, and afterward had a comfortable night.

The cause of the pain seems to be from the fact that children frequently have highly acid urine, due to the presence of uric acid; this, with possibly the small crystals of uric acid, being retained at the mouth of the urethra by the elongated prepuce, excoriates or irritates the mucous membrane. In fact, we have a urethritis established; we have also an inflammation of the mucous membrane of the prepuce itself. This irritation causes erection to take place in the glans through reflex influence, and the child is kept in constant pain until relief is afforded.

Now let me say a few words to you as regards the necessity of the operation of circumcision. My experience, which is quite a large one, enables me to say that if every child, shortly after birth, is taken in hand by a nurse or mother, and the foreskin pressed back, in a very short time it makes no difference how narrow the opening in the foreskin may be, all adhesions will eventually be broken up, and the mucous membrane be loose enough to allow full erection to take place; but, if this is neglected, as the child grows older it becomes very much more painful, and a very much more difficult operation. I believe it is nearly always possible to break up adhesions and to retract the foreskin, but at the same time I think that a child, at the age at which this one is, is placed in a far better condition in after-life by having the redundant foreskin removed and the ad-

lesions entirely broken up. The operation takes but a few minutes. I have never seen it followed by any bad effects, and ether will render it painless.

Now you will ask me, possibly, whether the many nervous troubles of which we read are ever the direct result of preputial adhesions or elongated foreskin. I think I can answer this in a very few words. I have never seen any lesions produced in the nervous system that I could directly trace to this condition; but I have seen phenomena the result of reflex irritation caused by phimosis that simulated serious disorders of the nutritive system, possibly acting through nervous influences. I have seen reflex symptoms of disorders resembling the hysterical phenomena of adults produced time and again, and let me tell you that hysteria is a common thing, even in infants; but the most frequent attendant upon this condition is a disturbance in general nutrition. The child will fail to grow stout and strong, despite all efforts on the part of the mother; nourishment seems to have but little effect upon it; it will fret, be peevish, flabby, and emaciated; the mother will worry, and tell you she thinks her child has worms, or that the milk does not agree with it. If you have satisfied yourself that it gets good food, you will ask whether it passes its water very frequently, and the answer will probably be, "Yes, doctor, baby is always wet." Here, then, you have the source of the trouble, and if you find an elongated prepuce, with a narrow opening excoriated at the end, reddened mucous membrane puckered up, I would advise you not to waste time, but to circumcise. The child will then grow strong and hearty; its flesh will become firm; it will sleep well; the restlessness will disappear; and you will be astonished at the change in its condition.

I shall operate on this child before you. You will notice that I draw the foreskin forward, and that this pair of self-retaining forceps grasps that portion which is in advance of the glans. I allow it to slant toward the dorsum so as not to cut the frænum. I will now take a sharp knife and trim off the projecting tissue, allowing the forceps to remain a few moments so as to permit the blood to coagulate thoroughly. When I take off the forceps and allow the skin to retract you will notice that I have made an annular excision of the skin about on a line with the corona. I will now, with a pair of sharp scissors, split up the mucous membrane on the dorsum and thoroughly retract the prepuce, breaking up adhesions with my thumb, and you will see that I have great difficulty in doing so. Having thoroughly broken up adhesions, I will now unite the edges of the denuded parts by means of a fine needle, using Snowdon's iron-dyed silk and making a continuous suture around the parts, so as thoroughly to approximate the edges. This takes, as you see, but a few minutes; the foreskin should remain retracted, and I very much prefer dressing it with dry dressing, using the borated absorbent cotton on the parts. In the hospital we usually dress these cases with carbolated oil, owing to the danger of suppuration.

While upon this I may speak about these cases of micturition at night. Children will get in the habit of wetting their beds for various reasons; first of all, it may be entirely the fault of the mother or nurse; the child will go to bed early and possibly no attention will be paid to it, and the bladder will become full either from sudden change in the temperature or an unusual amount of liquid food, or possibly some diuretic substance which it has taken during the day. The child will be in sound sleep and will pass its water; now this usually will be followed by a scolding, and the little sufferer, fearing a repetition of the offence and its consequences, will have it on its mind the next night on retiring, and, owing to the mental effect through reflex control, will contract the bladder at the same time.

Children are creatures of habit to a very marked extent; as we all know, the natural tendency in nature to perform its operations at certain definite periods soon makes it impossible for the child to control itself; the more it is scolded the more its mind will, during sleep, dwell upon this condition. Such cases should not be treated in a harsh manner, but by endeavoring, if possible, to change the hour of this function. If it takes place at nine or ten o'clock, the mother should invariably at that time lift the little one out of bed and put it on its chamber.

Unconscious micturition may again be caused by some local irritation. Constipation is a frequent cause, also worms, especially seat worms, preputial adhesions, eczema, etc.; each of these, of course, has its individual remedy. Then again, sometimes, indigestion will produce it; cerebral excitement, dreams, chilling of the body in the early morning hours with a resultant checking of the perspiration, also irritation of the bladder from over-acid urine or deposits of phosphates or oxalates; these should have their appropriate treatment. When nervous irritability or loss of control or irritation of the neck of the bladder is the cause, the child should be placed upon doses of belladonna, or bromides and chloral at night, or possibly give the belladonna in the mixture at bedtime, or belladonna in form of tincture, one or two drops twice or three times daily or oftener for a child two years old as indicated; frequently a suppository of quinine with belladonna is very useful at night upon retiring. The child, under such circumstances, should be placed upon a tonic during the daytime. The tonic that I usually advise in such cases is: wine of pepsin with Fowler's solution, or wine of iron with tincture of nux vomica, the former given after meals or a little before. The child should be kept out of doors, have nourishing food, and be well sponged twice a day with cold water and thoroughly rubbed in order to invigorate the system, which is evidently lowered in its tone.

ORIGINAL ARTICLES.

TWO CASES OF OPERATION FOR PYLORIC STENOSIS.[1]

By CHARLES McBURNEY, M.D.,
of New York.

It is not my intention to review or compare the different operations which have been devised for the relief of pyloric stenosis. I desire merely to present the results of my experience with the most recent of these operations. I refer to that devised by Professor Loreta, of Bologna, namely, digital divulsion of the pylorus. This operation is intended to take the place of excision of the pylorus, and is, of course,

[1] Read before the New York Surgical Society, Dec. 22, 1885.

applicable only to cases where the stenosis is due to cicatrization or chronic thickening of a non-malignant character. That such cases exist has been abundantly proven, and the records of pylorectomy, duodenostomy, and gastro-enterostomy all contain cases of this comparatively simple nature.

The operation of digital divulsion was first performed by Loreta on September 14, 1882, and with success. The patient suffered from dilatation of the stomach due to stenosis of the pylorus. The stenosis was believed to be due to the cicatrization of an old ulcer. (I derive my information on many points referred to in this paper from a translation of Loreta's article by Dr. Ancona, which is to be found in the *Arch. Gén. de Méd.* for September of this year, and from an interesting article on the same topic which may be found in the *British Medical Journal* for February 21, of this year. The latter is by Mr. Holmes. And in the *American Journal of the Medical Sciences* for April, 1885, is an article by Professor Randolph Winslow, in which the whole subject of pyloric stenosis is very carefully dealt with.)

The method of operating may be briefly described thus: Incision of the abdominal wall to the extent of about five inches on the right side, close to and parallel with the free border of the ribs. Opening of the stomach by a wound three inches long very near the pylorus, and about midway between the two curvatures. The introduction of one index finger through the pylorus, then the introduction of the other index finger, and finally the gradual forcible dilatation of the orifice to the extent of about three inches. Then immediate closure of the stomach and abdominal wounds. The probable immunity from hemorrhage, the short duration of the operation, and the excellent results which are reported as having followed the practice, would certainly seem strongly to recommend its adoption in suitable cases. I find it impossible to present anything like an accurate statement of the results of all the cases thus far operated upon by this method.

Winslow, in the article already referred to, summarizes the number of operations up to April of this year as six. Four of these were done by Loreta and two others by different Italian surgeons. Of these six cases, two died, but no mention is made of autopsy. The others were all successful. In Ancona's article the statement is made that Loreta claims to have performed the operation twenty-two times and *always* with success. Also that five other Italian surgeons have done the same operation successfully. It is difficult to reconcile these different statements, and I am not able to verify them, as many of the cases have not been published. It is doubtless true, however, that so far the operation of digital dilatation of the pylorus has been very successful, and the mortality low as compared with any other operation having the same object in view.

CASE I.—Marie B. Propes, aged thirty-nine, married, Virginian, was first seen by me in the early part of the present year. She had then been for some months under the care of Dr. F. P. Kinnicutt, at St. Luke's Hospital, who had carefully noted her symptoms and diagnosticated dilatation of the stomach due to stenosis of the pyloric orifice.

The patient gave the following history: From twenty years of age up to a year ago she suffered from attacks of what she called "bilious colic." These attacks occurred every few weeks, and were characterized by intense pain in the epigastrium extending to the back and by violent vomiting without blood. About one year ago she began to have frequent attacks of vomiting, these occurring sometimes twice a day, sometimes only once in two or three days. Nearly all food was vomited, and intense burning pain was felt in the epigastrium with continual thirst. For some five months the patient had been confined to bed, and had become very weak and emaciated. For seven or eight years before this period her weight had averaged two hundred pounds. Half of this weight had been lost within one year. Flatulence, eructations of gas, and obstinate constipation had been prominent symptoms for many months. No pulmonary or cardiac symptoms existed.

On admission to the hospital on February 4, 1885, the patient weighed less than one hundred pounds. The localized distention of the abdomen extended from just below the ensiform cartilage to a point three inches below the umbilicus, and to a point three inches to the left of the umbilicus, and two inches to the right. Over the whole of this region was marked tympanitic reasonance on percussion. After emptying the stomach with a rubber tube, a small movable tumor, about the size of an almond, could be felt on deep pressure, one inch to the right of the median line, and two and one-fourth inches above the umbilicus. The patient was put upon a diet of peptonized milk and beef peptonoids, and the stomach was washed out daily. On each occasion the washing was kept up until the fluid returned was perfectly clear. In spite of this lavage, vomiting occurred almost daily more than a month, and when a little rice had been added to the diet, particles of rice could be found in the washing five days after such a meal. Nevertheless, under this treatment the vomiting gradually subsided and the patient's weight steadily increased. The experiment of discontinuing the washing was then tried, but pain and vomiting almost immediately returned.

In this case, then, there was no history of ulceration. The enormous dilatation of the stomach was easily demonstrated by filling the organ with water, and then emptying it. The existence of obstruction at the pyloric orifice was also shown by the return of undigested food many days after it had been swallowed, and finally a distinct tumor could be felt at the exit of the pylorus. This tumor was believed not to be malignant from the facts that it did not increase in size during months of observation, that there was no true cachexia, and that the patient increased in weight many pounds while under treatment. No doubt she could have been kept alive with careful treatment, including daily washings of the stomach, for an indefinite period. She was anxious, however, to leave the hospital; was too nervous to manipulate the stomach tube herself; and desired some radical operation.

I desire to state here that the whole of the medical treatment of this patient had been conducted by Dr. Kinnicutt, under whose care the patient was, and

who, after consultation, requested me to operate upon the case.

Believing the case to be similar to those reported by Professor Loreta, and in which he obtained such signal success by forcible dilatation of the pyloric orifice, I determined to attempt the same procedure.

On July 3, the patient was put upon a diet of peptonized milk only, to prepare the stomach for operation. On July 6, the day of the operation, the stomach was thoroughly washed out with borax solution at 10 A. M., and again at noon. At 2.15 P. M., irrigation was practised with a solution of salicylic acid 1 part, boric acid 4 parts, and water 1500 parts. Before the second washing the fluid was found to be distinctly acid, and to contain some white material in suspension, which, after settling, left the fluid comparatively clear. The sediment consisted of oil globules, casein, and oval and polygonal epithelial cells. Ether was given at 2.30 P. M. on July 6, 1885, and the operation was conducted as follows: with the immediate assistance of my colleague Dr. Abbe, and in the presence of a number of surgeons and physicians. The surface of the abdomen was thoroughly cleansed. I made an incision about five inches long, from a point one inch below and one and a half inches to the left of the ensiform cartilage, downward to the right, parallel with the border of the ribs. All the tissues down to the peritoneum were divided as rapidly as possible, and all vessels tied. The peritoneum was then incised throughout the whole length of the wound, and the pyloric end of the stomach readily found and drawn out through the wound. No adhesions existed between the pylorus and the liver or pancreas. The small tumor already described was felt at once, and was evidently the thickened wall of the pyloric orifice. The anterior wall of the stomach, nearer the lesser curvature and just to the left of the pylorus, was clasped by two thumb forceps, the blades of which were covered with flannel, and incised to the extent of three inches. The pyloric orifice was easily found, but it was so contracted that I could not, even when using as much force as I dared, pass the first phalanx of my finger through it. It felt very much like the firm os of a normal uterus. For this emergency I had ready a rectal dilator, which seemed to be well suited for a preliminary stretching, having perfectly smooth, rounded blades. This was easily passed through the pylorus, but so great was the tenacity of the hypertrophied wall that it was only after repeated stretchings with this instrument that I was able to get one finger through I then passed in the index finger of the other hand, and, by forcibly separating the two for some time, stretched the opening to a long diameter of about three inches. It was then perfectly easy, on looking through the wound in the stomach, to inspect the dilated pylorus. A short tear in the mucous membrane was recognized, and a very little dark blood noticed, but no bleeding vessel. The mucous membrane of the stomach was then sewed with a fine silk, continuous suture, a straight, round needle being used. No bleeding worthy of notice had occurred in making the incision in the stomach wall. The serous coat was united by twelve interrupted catgut sutures introduced after Lembert's method. The peritoneum of the abdominal wound was then sewed with a continuous catgut suture, and deep and superficial catgut sutures were used to close the incision of muscles and skin. Three silver wire supporting sutures, with lead clamps, were used to give additional strength. An antiseptic dressing was applied over all. The operation, from the first incision to the complete closure of the external wound, lasted one hour and eighteen minutes.

The patient bore the operation quite well, and at 6 P. M. her pulse was fairly good. Still the evidences of shock were very noticeable, and from this time on both pulse and respiration rapidly failed. She died six hours after the close of the operation, although every effort was made by the members of the house staff and myself to sustain life.

An autopsy was held in my presence the next day. Excepting the stomach, the various organs were found to be in a healthy condition; the wound in the stomach was found tightly closed, so that on distending the stomach with water not a drop escaped. On opening the stomach it was found to contain some ten or twelve ounces of fluid blood. The mucous membrane of the stomach itself was deeply stained with blood; but no lesion other than the operation wound was to be discovered. The pyloric orifice was widely dilated so as easily to admit three fingers. In the mucous membrane of the pylorus on the posterior surface was a recent longitudinal laceration, about an inch long. This laceration extended through the mucous and submucous coats; otherwise the mucous membrane was normal, and no trace of old or recent ulceration could be found. Entirely surrounding the pylorus was a thickening of firm fibrous or fibrous and muscular tissue, which had doubtless caused the stenosis, and which had formed the small tumor previously described. The duodenum was found to contain a large quantity of blood, and many ounces of blood were found in the small intestine. The peritoneum, except where cut in the course of the operation, was normal. No adhesions existed at any point.

The behavior of the patient after the operation, together with the result of the autopsy, made it very clear that the patient had died of hemorrhage, the blood coming from a vessel involved in the tear of mucous membrane found in the pylorus.

Case II.—Susan Joyce, aged fifty-two, widow, Irish. The patient was admitted for the first time to St. Luke's Hospital on December 18, 1883. She then gave the following history: from fourteen to nineteen years of age she had occasional hæmatemesis. At the age of nineteen, after a severe exertion, she vomited a large quantity of blood during two days. Twenty years ago the patient vomited black grumous material nearly every day for a year, and always had severe pain in the epigastrium after eating. In the early part of 1881 she vomited a large quantity of blood. She was admitted to the hospital much emaciated, complaining of severe abdominal pain, which was much increased after eating, and which extended to the back and right shoulder. The stomach was found to extend to a point four inches below the umbilicus. After a short stay in the hospital the patient was dis-

charged, to be readmitted on April 9, 1885. Since leaving the hospital she states that she has been living upon milk and stimulants, with a little fish and eggs. She had continued to vomit daily. Usually the vomit had been of a dark green color, sometimes mixed with a little bright blood. Constipation had been extreme, no stool occurring without a cathartic. She had been confined to bed for the last six weeks, and had lost flesh and strength rapidly. The patient was found to be emaciated, anæmic, complaining much of thirst and constipation. Tongue coated, and urine scanty. Slight dulness was found at the right apex, and the patient had a cough and occasional fever and night sweats. The stomach was found to be much dilated, occupying the left umbilical, lumbar, and hypogastric regions, extending two inches below the level of the anterior superior iliac spines. Percussion over this area was resonant, with marked succussion sound. A distinct tumor, about one inch long and one-half inch broad, was felt in the epigastric region two and a half inches above the umbilicus in the median line. This tumor was not movable, and was firm and resistant. With the exception of the apex of the right lung the other organs were normal. The patient was put upon a diet of peptonized milk and beef peptonoids. Her weight at this time was eighty-seven pounds, certainly from thirty to forty pounds less than her normal weight. On April 8 daily lavage of the stomach was begun, the solution used being one of borax, twenty grains to the pint. Under this treatment the patient's weight increased to ninety-nine pounds at the end of June. At this date the capacity of the stomach was 115 ounces.

This patient also had been under the care of Dr. F. P. Kinnicutt, in the medical wards at St. Luke's Hospital, for nearly three months. During that time I examined her, with Dr. Kinnicutt, several times, and we agreed that, doubtless, the original cause of her troubles was ulcer of the stomach, probably situated at or near the pyloric orifice, as indicated by the presence of the small tumors found at that point. It seemed probable, too, that this ulcer had healed, or had become nearly cicatrized, from the absence of hæmatemesis during a long period. The tumor was not believed to be malignant, as it did not increase in size, and as the patient did not present any cachexia, and increased markedly in weight under treatment by lavage. Her case was not a promising one, but there was no reason to believe that her life could be prolonged without surgical assistance, unless she remained a permanent resident of the hospital. I determined, therefore, to make an exploratory operation, and, if possible, relieve the stenosis.

On June 20th, the patient's diet was limited to pancreatized milk only, to prepare the stomach for operation. On July 6th, the day of operation, the stomach was washed out at 10 A. M., and again at 12.30 P. M. The fluid removed before the second washing was decidedly acid, containing much whitish material in suspension, which did not completely separate. Under the microscope the sediment was found to consist of oil globules, coagulated casein, granular nucleated epithelium, and some mucus.

At 3 30 P. M. the stomach was again washed with the borosalicylic acid solution. The patient was etherized at 4.30 P. M. I had the kind assistance of my colleague, Dr. Robert Abbe, and, during the operation, all possible antiseptic precautions were used. The abdominal wall was incised in precisely the same manner as in the case first reported. All bleeding was controlled, and then the peritoneum was opened as before. The stomach was easily seized, but I found considerable difficulty in locating the pylorus. It was at last made out to be directed upward and somewhat to the left, its ordinary position being occupied by the dilated pyloric end. The stomach wall was then incised to the extent of two and a half inches, the incision being near the lesser curvature, and close to the apparently thickened pylorus. On opening the stomach an old and apparently healed ulcer was felt and seen directly opposite the incision. This ulcer was about one inch in diameter, and its largely thickened edge formed the tumor which had been felt before the operation. The base of this ulcer was firmly adherent to the pancreas behind, and the contraction of cicatrization had given the stomach an hour-glass form. Even then it was difficult to find the pyloric orifice. After a search of some minutes I found it at the upper border of the ulcer, close to the latter, but not involved in it, and directed upward. The posterior edge of the pylorus had been so firmly drawn by the cicatrization of the ulcer that although it was easy, on lifting the anterior edge, to pass the finger through it, yet when the anterior edge was not so lifted the orifice was completely closed. Had the patient's general condition warranted it, the operation of gastro-enterostomy would, I think, have been the better one; but, on account of her age and general feebleness, I did not think it wise to prolong the operation. I thought that by a thorough stretching of the pylorus I could counteract the stenosis produced by the cicatrized ulcer. When the two index fingers were introduced, the pylorus yielded very readily without tearing, so as to leave the exit from the stomach very free. The two fingers were separated during the stretching about three inches. I then at once sewed the mucous membrane of the stomach with a continuous fine silk suture, using a fine, round needle. The serous surfaces were united with a continuous catgut suture after Lembert's method. The abdominal wound was treated as in the first case, and an antiseptic dressing applied.

The time occupied in this operation, from the commencement of the first incision to its complete closure, was one hour and three minutes. The patient rallied very well from the effects of the operation. She slept comfortably nearly all night, receiving small quantities of brandy and ice, and two small hypodermic injections of morphine. But at the end of twenty-four hours her kidneys had excreted only twelve ounces of urine, which was found to contain two per cent. of albumen. Before the operation the urine had been normal, though scanty. From this time on the kidneys ceased to act, and the patient became gradually weaker, and respiration and heart action failed rapidly. She died thirty and one-half hours after the operation, the cause of death being apparently suppression of urine.

At the post mortem examination, which was made the next day, the following lesions were discovered: The left kidney was normal in size; the capsule was adherent at different points; a few small cysts were found in the cortex; the cortex was thin, and the whole organ congested and fatty; the right kidney was in a similar condition, and an infarction one-fourth of an inch in diameter existed in it; the upper part of the right lung displayed the lesions of advanced chronic phthisis; the lower part of both lungs were congested and œdematous; recent peritoneal adhesions existed in the immediate neighborhood of the abdominal wound; no escape of fluid from the stomach had occurred, and the wound in the stomach wall was tightly closed; the mucous membrane of the stomach bore plain evidences of chronic gastritis; posteriorly was a large, old ulcer, about one inch in diameter, mostly or entirely cicatrized; the base of this ulcer was firmly adherent to the pancreas, and its edge was much thickened; the pyloric orifice lay immediately next to the right and upper edge of the ulcer; the orifice was widely dilated, and no rupture of mucous membrane existed; the stretching seemed to have accomplished the object without injury to any adjacent part.

It is not always agreeable to listen to the details of unsuccessful cases; but, in relation to new procedures, unsuccessful cases possess a certain value, and I have therefore made these two the subject of my paper. The particular points to which I wish to call attention are the cause of death in the first case, and the manner in which stenosis was produced in the second.

ON METHODS OF TESTING THE DIASTATIC ACTIVITY OF MALT EXTRACTS.

By R. DORSEY COALE, Ph.D.,
PROFESSOR OF CHEMISTRY AND TOXICOLOGY IN THE UNIVERSITY OF MARYLAND, BALTIMORE.

In a recent number of The Medical News (September 5, 1885), Prof. Wm. L. Dudley, of Cincinnati, has described a method of testing the relative diastatic activity of malt extracts, and has given a table of comparative results obtained by him in thus testing samples of several malt extracts of the most prominent manufacture found in the market.

Inasmuch as extract of malt is at present being very largely prescribed by physicians for its diastatic effect, the question as to the relative diastatic activity of different samples of malt extract, and the best means to be adopted in deciding this question, are by no means unimportant matters to the profession. Now, the results obtained by Prof. Dudley, as given in his table on page 259 of The News, are so utterly at variance with those obtained by myself and by others in a very large number of experiments, conducted at various times for more than a year past, and his method of testing appears to me to be so very untrustworthy, that, in view of the importance of the subject, I do not think his paper should be allowed to pass unquestioned.

In the first place, as to the method of testing adopted. The method employed by Prof. Dudley consists, essentially, in mixing a given quantity of each extract with equal quantities of starch paste; maintaining the mixture at a temperature of 65° C., and from time to time removing a drop of each mixture and testing it "with iodine solution on a porcelain plate or watch-glass, or in a small vial." This testing is continued from time to time until a drop of the mixture of starch and malt extract remains "nearly colorless" when tested with the iodine solution, which, as Prof. Dudley says, "will complete the action,"—that is, the conversion of the starch by the diastase of the malt extract. The time required for this conversion is noted in each case, and the malt extract valued accordingly, the best, of course, being that which has required the least time for the conversion of the starch.

Now this method of testing with iodine solution may, under proper conditions, answer as a qualitative test of the presence of diastase in a malt extract, but I have fully satisfied myself by a number of very careful experiments that, as a means of quantitative or comparative testing of the diastatic activity of different extracts, it is absolutely worthless, and in the highest degree untrustworthy, and the results obtained by its use are conflicting and contradictory. Moreover, it has been shown by J. Kjeldahl (Dingler's *Polytech. Journ.*, 235, p. 379), that determinations of diastatic action are only of comparative value when the amounts of starch used are considerably in excess of the amount converted by the action of the diastase, and that the iodine reaction does not fail until the formation of sugar ceases, at which point there is no longer such an excess of starch present.

Prof. Dudley quotes Payen as authority for the statement that the action of diastase upon starch "continues only until 51 per cent. of the starch has been converted into a mixture of maltose and dextrine, at which point it ceases until the maltose has been removed." It has, however, been shown by O'Sullivan (*Journ. Chemical Soc.*, 1872), Kjeldahl, and other more recent observers, that this statement of Payen is erroneous, and that a conversion of from 66 to 68 per cent. is easily accomplished by diastase, and that the action does not entirely cease even at this point, but still proceeds, though very slowly, until the starch is entirely converted; and that the presence of maltose has no influence whatever upon diastatic action.

Beyond all question the best method for the comparative testing of the diastatic activity of malt extracts is that which has been generally employed by all observers, and which consists in directly determining the amounts of sugar formed by a given amount of the extracts from a large excess of starch in a given time.

After a good many experiments, to determine the most favorable conditions, I have finally settled upon the following method of procedure as giving the best results, and being the most convenient in practice.

A 5 per cent. solution of the extracts to be tested is made by dissolving 5 grammes of the extract in 100 c.c. of water; 5 c.c. of this solution (containing 0.25 gramme of malt extract) is added to 250 c.c. of 3 per cent. starch paste, formed by adding 30 grammes of Bermuda arrowroot to 1 litre of boiling distilled water, and allowing the mixture to cool.

The various mixtures are then carefully kept at the same temperature of 55° to 60° C., by immersion in the same water-bath, or other suitable means, for thirty minutes. At the end of this time the action of the diastase is stopped, either by raising the temperature to the boiling point, or, better, by the addition of 2 or 3 c.c. of a 10 per cent. solution of caustic soda. The mixtures are then carefully diluted to a given volume, and the amount of sugar in each determined by means of a standard Fehling's solution. The amount of sugar contained in the malt extract added is also determined, which amount is to be deducted from the total amount found after digestion with the starch paste; the remaining amount of sugar is that which has been formed from the starch by the action of the diastase, and the relative amounts found in the several cases represent directly the relative diastatic activity of the several malt extracts.

It is absolutely essential that the starch paste should be prepared as directed above. Bermuda arrowroot is almost the only form of starch obtainable in the market which is not more or less alkaline, and it seems to be almost impossible to remove this alkalinity by washing.

It has recently been shown by Duggan (*Amer. Chem. Journ.*, vol. vii., No. 5) that the amount of sugar formed is only directly proportional to the amount of diastase present when the solution is perfectly neutral; and that the amounts of sugar formed by a given quantity of malt extract from ordinary starch and from arrowroot, under exactly similar circumstances, may differ by as much as 90 per cent.

The use of ordinary hydrant-water in place of distilled water in preparing the starch paste, may, according to Duggan, occasion a difference of 40 per cent. in the amounts of sugar produced.

Of course, the amounts of malt extract and starch paste used may be increased or diminished as desired, but I believe that the quantities given above will be found to be the most convenient in practice, and under no circumstances must the proportion of starch to malt extract be less than that given above (28 : 1). It may even possibly be found that, in some cases, this proportion is too low, and if in any experiment the amount of sugar produced should be found to be equal to one-third of the starch used, the experiment should be repeated with an increased proportion of starch to malt extract.

I have carefully tested, according to the method just described, samples of the first five brands of malt extract given in Prof. Dudley's table, and the results are given in the table below. In order to obtain samples which should, as nearly as possible, represent the quality of the malt extract at present being put upon the market by the several manufacturers, and to obviate any possible deterioration which the extracts might undergo with age, the samples used in my experiments were obtained from a large wholesale house in this city, and were the freshest on hand at the time. As neither the W. S. Merrell Co.'s extract nor Forbes's "Liquor Diastase" could be obtained in Baltimore, samples of these preparations were obtained direct from the manufacturers through the agency of the wholesale house just mentioned.

The following are the results obtained:

Name.	Weight of maltose produced
Maltine	0.612 gramme.
Forbes's Liquor Diastase	0.407 "
W. S. Merrell Chemical Co.'s Extract of Malt	0.232 "
Trommer's Extract of Malt	0.132 "
Keasbey & Mattison's Extract of Malt	apparently no action.

I had already found, in previous experiments, that the remaining three brands of malt extract mentioned in Prof. Dudley's list, have no diastatic power, and, therefore, did not consider it necessary to include them in these experiments.

It will be seen that my results present certain wide differences from those obtained by Prof. Dudley; notably in the case of Maltine. The figures given above are so completely in accordance with the results obtained by me in very numerous experiments which I have had occasion to make heretofore with this preparation, that I am certain of their correctness, and the very remarkable result obtained by Prof. Dudley ("apparently no action in three hours") can only be accounted for by the supposition that he has used in his experiments a sample of Maltine in which the diastase has been, by heat or otherwise, accidentally destroyed.

It is a perfectly well-known fact, of which any physician can easily satisfy himself in a very few minutes, that Maltine does have a very decided and rapid action upon starch, and Prof. Dudley's statement is in no way a fair one as regards the quality of this preparation as placed upon the market by the manufacturers.

In Prof. Dudley's experiments the proportion of starch to malt extract used (4:1), is far too low; this is shown by the fact that, taking his own statement that "the iodine reaction fails as soon as the saccharification has affected a quarter of the starch" as correct, he has obtained in thirty-nine minutes with his best preparation (Forbes's), a conversion of only one part of maltose to one part of malt extract, whereas in my experiments I have obtained, with the same preparation, more than double this amount of conversion in the same time.

Moreover, since no especial mention is made upon the point, it is probable that Prof. Dudley used in his experiments ordinary alkaline starch, which would still further diminish the amount of maltose formed, and utterly destroy the comparative value of the experiments.

To show how very great an effect the use of ordinary starch has upon the result of these experiments, I have repeated them as before, using in this case, however, starch paste made from ordinary starch and hydrant water, in place of that made from arrowroot and distilled water used above, and 0.5 gramme instead of 0.25 gramme of each of the preparations.

In this case the following results were obtained:

Name	Weight of maltose produced.
Maltine	0.490 gramme.
W. S. Merrell Chemical Co.'s Extract of Malt	0.217 "
Trommer's Extract of Malt	0.114 "
Forbes's Liquor Diastase	0.113 "

It will be noticed by these results that, not only is the amount of sugar produced very much diminished by the use of ordinary starch, but that the relation existing between the amounts formed by the various preparations is altogether changed. This is most probably due to the fact that the varying amounts of acid contained in the several malt extracts serve to neutralize, more or less completely, the alkalinity of the starch, and according as this neutralization is more or less completely effected, so will a greater or less amount of sugar be produced.

It has been stated above that in neutral solutions, with a large excess of starch, the amount of sugar produced in a given time is directly proportional to the amount of diastase present; to illustrate this, I give the following table of results obtained by Duggan in allowing varying amounts of a 5 per cent. solution of malt extract to act upon starch for thirty minutes at a temperature of 55° C.

c. c. of 5 per cent solution of malt extract.	Weight of maltose formed.	Weight of maltose per c. c. of malt extract used
1	0.475 gramme.	0.475 gramme.
2	0.937 "	0.469 "
3	1.381 "	0.460 "
5	2.269 "	0.454 "

The figures in the first column give the number of cubic centimetres of 5 per cent. solution of malt extract used in each case; those in the second column give the total amount of maltose produced, while those in the third column show the amount of maltose formed per cubic centimetre of malt extract solution used in each of the experiments, and this amount is seen to be very nearly equal in each of the four experiments; that is, the total amount of maltose produced is very nearly directly proportional to the amount of malt extract used.

The statement which Prof. Dudley makes, that in the case of five extracts which showed practically no diastatic properties, "in two cases as much beer, and in the others an equal amount of molasses, would be of almost, if not quite, as much benefit to the consumer," also deserves some notice.

While it is likely that rather too much importance has been attributed to malt extract as an article of food, the extended experience of Dr. Milner Fothergill and others has shown, beyond all doubt, that its value in this respect is much greater than Prof. Dudley seems to suppose, and his statement quoted above is by no means borne out by experience.

It is proper that I should state, in conclusion, that these experiments have been undertaken solely on account of the importance of the subject to the medical profession and the public, and without the suggestion or knowledge of any manufacturer.

Chemical Laboratory of the University of Maryland,
Baltimore, Nov. 1885.

ON THE INCURABILITY OF CERTAIN NERVOUS AFFECTIONS OCCURRING AMONG SYPHILITICS.[1]

By R. W. Amidon, A.M., M.D.,
of New York

The writing of this paper originated from a conviction in my mind, in the first place, that syphilis is by many overrated as an etiological factor in nervous diseases, and, in the second place, that when a history of syphilitic infection can be made out, it leads many to give a more favorable prognosis than the real pathological condition warrants.

The first error arises partly from the fact that syphilis, like malaria, is a convenient peg to hang a disease on, but more, I think, because equally important factors in the production of organic nervous diseases, such as alcohol, tobacco, sexual excesses, worry, exposure, etc., are lost sight of; the second error consists in the fact that there occur, among syphilitics, obscure nervous diseases which seem to be, but are not, of a specific nature, and also because some ignore the fact that, while syphilitic growths are tolerably amenable to treatment, the pathological conditions which their presence excites are not so curable. A gumma may be absorbed, but the destruction its pressure has caused, or the vascular changes it has brought about, vanish slowly, if at all. An endarteritis may subside, but the necrotic softening, the vascular occlusion caused, is incurable.

To illustrate my meaning better, some cases from my practice will be briefly cited, which have many features in common. They all had suffered an indubitable specific infection; they all, at a period remote enough to suppose the tertiary stage had been reached, developed alarming nervous symptoms; and they all were submitted to thorough mixed treatment with varying success, but no cure.

Four cases are cerebral, two are cerebro-spinal, and four are spinal.

Case I. *Recurrent gumma, producing aphasia and epilepsy; cured. Periencephalitis, secondary to the gumma, causing partial right hemiplegia and dementia with tremors; not cured.*—A married business man, thirty-two years of age, consulted me in the winter of 1882 for aphasia and headache. He had contracted syphilis at seventeen, and had always abused alcohol and tobacco.

In the summer of 1880, when thirty, after some weeks of general malaise and dull headache, he had his first epileptic convulsion. A month later he had a second. He was put on treatment (probably specific) by his doctor and remained well for six months, when he had several partial attacks without loss of consciousness. When thirty-one, he noticed a return of headache with thickness of speech, and had another severe convulsion. Again several weeks of mixed treatment apparently cured him, and he stopped taking the medicine. When he consulted me he said that, some days before, left hemicrania had come on, with a dizzy feeling toward night. In the last few days his speech had become thick, and he had caught himself using wrong words.

I found him rather cachectic, with a stupid facies and thick speech. His optic nerves were normal, but he had a marked right hemiplegia.

After two weeks of mixed treatment, the headache disappeared, speech was fairly distinct, the weakness of the left side was only to be detected by the dynamometer, and he seldom made aphasic mistakes, except when tired at night. No further improvement took place, and there remained a slight right hemiparesis and a perfectly appreciable degree of de-

[1] A paper read before the Section on Neurology of the New York Academy of Medicine, December 11, 1885.

mentia, shown by dislike and inaptitude for business, inattention to surrounding affairs, disinclination to talk, thick speech, and expressionless facies.

Remarks.—In this case the gummy growth causing the aphasia and epilepsy was cured, while the secondary cerebral destruction and periencephalitis, causing hemiparesis and the dementia, were not affected. It shows the recurrent tendency of such growths and the necessity of prompt, thorough, and continued treatment

A gummy tumor, itself curable, if overlooked or inefficiently treated, does damage which is incurable. By unrelieved pressure it destroys nervous elements which cannot be replaced, and by constant irritation it excites a meningitis of a low grade which irreparably damages the subjacent nervous substance.

It was once my good fortune to see the brain in a case in which a gummy tumor, causing hemiplegia, epilepsy, and coma, had been removed by thorough mixed treatment. The patient died of nephritis and the depression in the convolutions, formerly occupied by the gumma, was filled by loose, œdematous connective tissue.

CASE II. *Gumma on humerus; cured. Occlusion of (probably) the left lenticulo-optic artery. Partial right hemiplegia and anæsthesia. Right hemichorea.*—Mrs, F., thirty years of age, consulted me in the summer of 1881 for a tremulousness of the right side. When twenty-four years of age, she contracted syphilis from her husband. When twenty-seven, while under treatment for syphilis, she had left hemicrania and a rather sudden loss of power in the right arm and leg with numbness, but no loss of consciousness or aphasia. A pretty complete recovery took place under mixed treatment and electricity. After the apoplectic attack she walked and used the right hand, but not for fine work. When she became excited, her whole right side trembled violently. Examination revealed a slight paresis and anæsthesia of the right upper and lower extremities, which were warmer than the left, and moist.

After being under observation about a month, she began to complain of pain about the right elbow, first nocturnal and then continuous, but worse in bad weather, followed by numbness and impaired tactile sensibility in the right forearm. Examination revealed a sensitive node on the right humerus under the triceps tendon. Mixed treatment promptly dispelled the node and its attendant phenomena, but had not the slightest effect on the cerebral trouble.

Remarks.—There was in this case probably a syphilitic endarteritis leading to thrombosis, and consequent necrotic softening in the region of the left lenticular nucleus, judging by the hemianæsthesia, and transitory slight paralysis followed by hemichorea. This thrombosis, whether syphilitic or not, left an incurable lesion, while the frank gumma on the humerus yielded speedily to specific treatment.

CASE III. *Occlusion of a branch of the left Sylvian artery. Partial right hemiplegia, anæsthesia, and aphasia. Hemicrania and petit mal.*—Mr. L., forty years of age, consulted me in the winter of 1882. When thirty-two he contracted syphilis, and besides had had repeated sores and gonorrhœas. Had been given to sexual excesses. Five months before I saw him there commenced a numbness in the right thumb which invaded the whole hand, and in fifteen or twenty minutes he lost the power of speech. Fifteen days later he had an apoplectic attack When he recovered and since, he noticed a loss of power in the right hand. His difficulty of speech was variable, and consisted chiefly in a hesitancy. The word "three" annoyed him especially. He had headache and one to ten "dizzy spells" a day.

Examination revealed great weakness of the right face and arm, with anæsthesia. The left optic nerve was normal, the right fundus was hidden by a cataract dating from childhood.

Remarks.—In this case there undoubtedly was widespread endarteritis, perhaps most marked in the left internal carotid, with complete occlusion and thrombosis of one of its terminal branches.

The variability of his impairment of speech is an exemplification, in a modified degree, of the so-called intermittent aphasia—supposed by some to be pathognomonic of syphilis. It probably is produced in this way. The centre for speech, we will say, is already anæmic, because of the gradual narrowing of the lumen of its nutrient vessel by specific endarteritis. So long as a strong heart with a high arterial tension is present, enough blood is forced through the narrowed vessels to maintain the nutrition and consequent function of the part. A marked fall of intravascular pressure, however, leaves the part supplied by the narrowed artery almost bloodless, and a consequent suspense of function or aphasia ensues.

CASE IV. *Probable periencephalitis. Headaches, insomnia, loss of memory, hallucinations, impaired speech, tremulousness, epileptiform attacks. Dementia.*—A machinist, thirty-three years of age, consulted me in August 1882. He contracted syphilis when twenty-one. Besides his regular duties he worked hard and late, when he should be resting, at designing and constructing naval engines. For some time he had had headaches, relieved by mixed treatment.

In the year preceding his call on me, he had been excessively annoyed by insomnia, loss of memory of recent events, hesitant speech, and omission of words and letters in writing. He had also noticed a dilatation of the left pupil.

Three months before I saw him his general headaches had returned, and he had become very headstrong and restless.

On examination I found his facies dull, his speech slow, thick, and hesitant. There was slight ptosis of the left eyelid and dilatation of the left pupil, which was sluggish to light. The tongue was protruded slightly to the right and was finely tremulous. A doubtful paresis of the right face was also present. There was a crepitus between the fingers. The knee reflexes were exaggerated. Both optic nerves were blurred. Thorough and persistent mixed treatment availed nothing.

He became more irritable, noises particularly disturbing him. His sleep remained poor and he had hallucinations of sight when his eyes were closed, which amounted at times to terrible visions. He complained much of dull pain behind the ears, in the occiput and back of neck. At times would stagger

and feel dizzy. A subsequent examination of the eyes showed his vision to be $\frac{6}{xxx}$ which, with + 1.5 s., was brought up to $\frac{6}{xx}$. He had an insufficiency of the externi of two degrees for the distance. The left disk was very much blurred, the right only fairly defined.

In the second month of my observation he had two "faint spells" while playing cards. He let the cards fall from his hands; could not talk for an hour; felt weak, and lay down. He dropped things with unusual frequency, forgot friends' names, and did not seem to understand as well as formerly. On his last visit to my office he sat familiarly on my desk.

When away in the country, his letters one day were faultfinding and abusive, the next day repentant and apologetic. They always contained many erasures, omissions of words, incoherent sentences, and much horrible spelling.

Remarks.—In this case there was undoubtedly a diffuse periencephalitis due, probably, both to his close application and syphilis, and he presented an almost perfect example of general paresis.

Case V. *Occlusion of the left lenticulo-optic or terminal branch of the left Sylvian artery. Posterior spinal sclerosis. Partial right hemiplegia and hemianæsthesia. Slight dementia and occasional maniacal attacks. Ataxia.*—A teacher, forty-three years of age, consulted me in the spring of 1883. When thirty-three, he had contracted syphilis. When forty-two years of age, serious nervous symptoms developed in the following order: There first appeared a heaviness of the legs and numbness, marked in the feet, slight in the fingers. He noticed an inequality of the pupils, and at times a dimness of vision. Tendon reflex was present at the knees at this time, but was slight. He was sleepless, depressed, and irritable, much worse in bad weather. Later, he had diplopia on looking to the left, and some aching pains in the legs, mid-dorsal region, bladder, and rectum. A short time before I saw him, after a few days of headache, he awoke one morning with a numbness of the right side throughout, with a marked weakness of the right arm and leg. Any misstep caused much vertigo, worse on the left side of the head.

At this time there was a marked right hemiparesis of the face, arm, and leg, and a moderate anæsthesia of the same distribution, with a peculiar scalded feeling in the right finger-tips.

He had no knee reflex, stood well with eyes closed, and his walk was rather kicking and stamping. He talked in a hesitant way, and made some mistakes. His ocular movements were good, although his interni were weak. The outline of his right optic nerve was very much blurred.

He became very morose, uncommunicative, capricious, headstrong, and, his wife says, at times abusive, unnatural, and almost violent. Under vigorous mixed treatment, the hemiplegia *almost* vanished; the anæsthesia, ataxia, and mental peculiarities remained unchanged.

Remarks.—Prompt treatment in this case probably resolved an endarteritis and prevented any further destructive processes. The necrosis which had occurred, of course remained. The persistence of mental peculiarities suggested the presence of a slight periencephalitis, which I have no doubt existed. Whether the spinal lesion was anything more than the sclerosis that often goes with periencephalitis, I cannot say; but it must have been much more marked in the posterior columns than elsewhere.

Case VI. *Periencephalitis and disseminated cerebro-spinal lesions. Dementia, tremors, impaired speech, impotence, and irregular paraplegic symptoms. Very marked and precocious arcus senilis.*—An artisan, thirty-eight years of age, consulted me in the summer of 1883. For years he had abused alcohol and tobacco. When nineteen, he contracted syphilis. When twenty-eight, he was almost beaten to death by four ruffians. In his thirty-third year, his speech began to get slow and thick, and he suffered much from tinnitus and vertigo. At the same time, he found his legs not as useful as formerly, being weak and uncertain, especially at night. His feet shuffled and dragged, and, when tired, there were pricking sensations below the knees. When thirty-five, complete impotence supervened, preceded by an interval of sexual excitement, during which he had intercourse two or three times each night. Since his thirty-sixth year, he had had precipitate micturition and sometimes an intense desire to pass water, with retention and dribbling. Very seldom, he had pricking pains in the legs and occasional pain across his brow. When thirty-seven, he had a temporary diplopia. His bowels became constipated after his legs failed, he thinks, from lack of exercise.

I found him pale, and with brown macules of large size in various parts of his body. His legs, with exaggerated reflexes and some hyperæsthesia, were strong, but he could not walk without help. His hands were strong, but both were slightly ataxic and hyperæsthetic. There was atrophy of each first interosseous muscle and each hypothenar eminence. The pupils were equal and responsive, there was a very marked arcus senilis, and the optic nerves were normal. The tongue was coarsely fibrillary, the speech thick and slow, and the facies dull. Thorough mixed treatment and entire rest produced no amelioration.

Remarks.—There probably were in this case disseminated cerebro-spinal lesions of the sclerotic type, and it is my opinion that sexual excess, the abuse of alcohol and tobacco, and the shock from his severe beating had as much to do with the production of his disease as the more remote syphilitic infection.

Case VII. *Central myelitis. Paraplegia. Impotence. Blindness. (Tobacco?)* — A messenger thirty-eight years old, contracted syphilis when thirty-three. He had always been nervous and had abused tobacco. He never could see very well with the left eye. At thirty-five his sight began to fail, and precipitate micturition, gradually growing worse, began to trouble him. Later, constipation appeared, and one attack of retention of urine. Two months before seeing me, sexual appetite and power left him, and he began to notice a weakness in the legs with stiffness, made worse by walking. He had some sharp shifting pains in the scalp.

His left pupil was dilated, the left optic nerve white and the right paler than normal. He had exaggerated knee-reflexes and his walk was spastic and dragging. There was no ataxia or anæsthesia.

Remarks.—The central myelitis, in this case causing paraplegia and impotence, might have been, but probably was not, dependent on syphilis. The patient was of a nervous temperament and by occupation was much exposed to the weather. The atrophy of his optic nerves causing his impairment of visual power might be accounted for by his abuse of tobacco.

CASE VIII. *Right hemimyelitis. Spastic paralysis of the right leg with perhaps exalted sensibility. Anæsthesia of the right leg, thigh, and side.*—A laborer contracted syphilis when twenty-three. He was hard-working and much exposed to changes of temperature. Four months before he consulted me, when thirty-five, nervous symptoms appeared in both lower extremities but in a different way. On the left side there first appeared a numb, sleepy feeling in the left foot, which in twenty-four hours ran up to about the level of the ribs. There was also a slight weakness of the left leg and a feeling as though the left sole was spongy.

On the right side there was first noticed a loss of power in the leg and a slight, sleepy feeling in the great toe. He thought the right leg stiff, as well as weak. At first he had involuntary defecation and retention of urine, which passed away.

The numbness on the left side later crept a little higher and there developed into a partial cincture feeling in the upper left abdominal region. There was a good deal of spinal trepidation in bed if excited.

His walk was springy on the right leg, and he swung the left. The right knee reflex was exaggerated. There was a partial anæsthesia in the numb areas, but no atrophy on either side.

Treatment availed nothing. The lesion involved principally the right half of the cord, as on the right side the motor and on the left side the sensory functions were most impaired.

Remarks.—The lesion, I surmise, was primarily a hemimyelitis turning into a patch of sclerosis. In its etiology, I think, syphilis played a minor part.

CASE IX. *Chronic atrophy of the cells of the anterior horns of the spinal cord. Rheumatic arthritis. Progressive muscular atrophy. Articular deformities.*—A woman nursing a patient with secondary syphilis contracted the disease at the age of fifty-nine. Four years later she began to have rheumatic pain in the shoulders, later in the elbows, and later still there were soreness and numbness of the hands. Four months before I saw her, a slight swelling commenced on the dorsum of the head of the second metacarpal bone and ulnar deviation of the fingers, and also a falling away of the first interosseous space of the right hand. Soon after, the same changes began in the left hand, and a falling away in the forearms was noticed. The patient had noticed that the wasting had been fibrillary.

When I saw the patient at the age of sixty-four, she had the ordinary deformities of rheumatic arthritis and muscular atrophy, of the progressive type, chiefly involving regions of both upper extremities.

Remarks.—This woman's hard work and old age entitled her to both rheumatic arthritis and progressive muscular atrophy, independently of the syphilis, which, I think, had nothing to do with either.

CASE X. *Posterior spinal sclerosis. Locomotor ataxia.*—A business man contracted syphilis when twenty-one. He had been overworked when a boy. When thirty-three, he began to complain of numbness and some loss of power in the legs, the left first. At the same time he noticed slowness of micturition and failing virile power.

He consulted me in the winter of 1882, a case of locomotor ataxia—of such a typical nature that it need not be detailed. Anti-syphilitic treatment, of course, was inefficacious. Of the relation between posterior spinal sclerosis and syphilis, more will be said anon.

Of these ten cases, eight were men and two were women. One women was infected by her husband, one by a patient, one man was innocently infected by a cut on the finger; the rest contracted the disease in the orthodox way.

The average age at infection was twenty-eight years, the earliest was at seventeen, the latest (the nurse) at fifty-nine.

The average period of incubation, supposing the nervous disease to have been tertiary, was nine years; the shortest time being two, the longest fourteen years.

The pathology of these cases is widely different. Two, among other lesions, had frank gummata, which promptly yielded to specific treatment.

Three cases had symptoms and a mental state pointing to a periencephalitis. One abused alcohol and tobacco; one abused alcohol and tobacco and was once nearly beaten to death, and was very degenerate, with an arcus senilis at thirty-eight; and the third was a rather precocious inventor. All might have committed, what to them individually, were sexual excesses. With some scepticism in my mind as to the etiological importance of syphilis in these cases, I am sure it found powerful synergists in alcohol, tobacco, sexual excess, mental strain, etc., or, at any rate, that the periencephalitis is not itself specific, but secondary to a syphilitic lesion, which may have been cured. Periencephalitis from any cause has a bad prognosis, provided we except some cases of transient dementia due to alcohol or the bromides. Periencephalitis in syphilitics I do not consider any exception to the rule, and is just as incurable as any.

Dr. Goldsmith, Superintendent of Danvers Asylum, in a very able paper on syphilis and insanity,[1] which I would like to quote at length, says:

"When a patient with symptoms indicating progressive paresis has a previous history of syphilis, I think he is more likely to have paresis without being more likely to recover from it; and in my experience, active treatment by mercury and iodide of potassium usually has a debilitating and injurious effect. The same is true of all

[1] Syphilis and Insanity, by W. B. Goldsmith, M.D., Boston Med. and Surg. Journ., November 5, 1885.

forms of mental disease which are not preceded by severe headaches, paralysis of limited groups of muscles, or localized disorder of sensation—that is, by symptoms indicating a circumscribed new growth. When such symptoms exist, the frequent efficacy of adequate anti-syphilitic treatment is unquestionable, and I have no doubt that mental disease can be averted by its employment."

Three cases had rather sudden hemiplegic symptoms, caused by arterial occlusion or rupture. When this is due to syphilis it depends on an endarteritis obliterans, leading to gradual encroachment on the lumen of the vessel, final thrombosis, and consequent necrotic softening. The frequent apoplectic onset in these cases is explained in the same way as is intermittent aphasia, by a weak heart suddenly failing to force enough blood through the constricted vessels to nourish the part.

Syphilitics are as liable to simple embolism, thrombosis, and hemorrhage, as other patients; and, of course, these conditions must be excluded. However curable the syphilitic endarteritis may be when treated promptly, the acute softening following unrelieved thrombosis, or the subsequent cicatricial changes, are not one whit more curable because syphilis thickened the vascular walls. The destructive process extends, or reparative changes take place, subject to ordinary laws.

Mixed treatment undoubtedly brings about vascular changes that check the morbid process and render a recurrence less likely. In all these cases a partial right hemiplegia and anæsthesia remained, proving the existence of a destructive lesion.

Two cases had spinal, in addition to cerebral, lesions, which in only one case were typical. Case V., in addition to his evident cerebral thrombosis, had probably a sclerosis of the posterior columns of the cord; while Case VII., superadded to a periencephalitis, had a doubtful disseminated sclerosis.

Three cases had spinal lesions only. One had a central myelitis, one progressive muscular atrophy, and one posterior spinal sclerosis. These may be attributed to any one of many causes, as well as syphilis. The question arises, Does rebelliousness to mixed treatment argue at all against the syphilitic origin of lesions? Why expect destructive lesions resulting from vascular disturbance to disappear any sooner because syphilis altered the vessels? Nervous tissue destroyed by disease, be it specific or simple, is rarely regenerated.

The question for us to decide, in preparing to make a prognosis, is: Has a destructive lesion occurred; and, if so, where is it located, and what is its extent? Indications of a destructive lesion should lead one to a cautious prognosis as regards perfect recovery, while the prognosis for life and a moderate amount of health may be good. A gummy intracranial or spinal growth giving rise to alarming symptoms, may vanish, as by magic, upon prompt treatment. The symptoms of these frank, specific growths are, as a general thing, characteristic and widely different from those of the more insidious destructive lesions.

An intracranial gumma often heralds itself by sharp, localized headache, gradually deepening paralysis, aphasia, epilepsy, and optic neuritis; while destructive lesions are more apt to have diffuse, dull headache, stationary or lessening paralysis, or aphasia, rarely epilepsy or optic neuritis. Intraspinal gummata give rise to a painful paraplegia, while an inflammatory or destructive change gives rise to various and atypical sensory and motor manifestations.

As to the pathology of these cases, I can say but little, as such a discussion opens the whole subject of the pathology of syphilis. This I will say, that, so far as can be told without autopsies, no permanent pathological condition was present in these cases which might not have been brought about by other etiological factors which were often present. The periencephalitis might be caused by alcohol, mental strain, or excesses: the arterial occlusion might be due to precocious disease not specific.

Two pathological conditions present in these cases, I think, are preëminently not of syphilitic origin. I refer to the chronic atrophy of the anterior horns in Case IX., and the posterior spinal sclerosis in Cases V. and X.

Syphilis has enough to bear, but I think it should not be made to shoulder true progressive locomotor ataxia. The late lesions of syphilis are focal or diffuse, not systematic; and, though multiple, are very rarely symmetrical. They may implicate one or both sensory tracts at a certain level, giving rise to sensory or ataxic phenomena, but not of the regular locomotor ataxia type; and it is unreasonable to suppose that syphilis will pick out bundles of fibres in the posterior columns and produce in them a symmetrical, equable sclerosis throughout perhaps the whole cord, leaving entirely intact every contiguous structure, and every other part of the cord. Of late, especially, the profession seems to cling tenaciously to the syphilitic etiology of tabes dorsalis, ignoring entirely the excesses, exposures, and mental or physical strains so often present. Donkin, in an able paper, says:[1]

"Syphilis, that inexhaustible cruse of ætiological oil, may be regarded as having been weighed in the balance of causation and found wanting. Recourse was, doubtless, had to it, with that natural longing for finality and logical rest which characterizes the minds of most of us; but, both on account of the wide prevalence of syphilis and the known habit of its morbid deposits, *which do not make choice of functional tracts*, its supposed causative *rôle* in locomotor ataxia cannot be at all satisfactory to the serious inquirer. The suggestion, in order to remove a difficulty from the syphilitic theory, that the morbid process may have been first diffused over the cord, and afterwards become localized in the posterior columns, is somewhat gratuitous, and certainly quite out of accord with the clinical history of most cases of ataxy.

"But, though the origin of this disease is confessedly obscure, there would appear to be some points of probability in the older notion, that it may lie in what is, to the affected individual, relatively excessive sexual excitement."

These remarks seem to me extremely sensible, and come to my mind with great weight. Leaving theoretical discussions aside, a study of the foregoing

[1] Suggestions as to the Ætiology of some of the So-called Systematic Diseases of the Spinal Cord, by H. Donkin, M.B., F.R.C.P. The Brain, Jan. 1883.

cases emphasizes the fact that treatment of nervous affections among syphilitics must be prompt and persistent to be successful, as postponed or spasmodic treatment often allows irremediable destruction to take place. With this fact in mind, can we say to ourselves that we protect syphilitics as well as we should against grave nervous diseases?

My opinion is that it is the duty of physicians to warn every syphilitic patient of the danger he is in of developing at any time grave nervous symptoms. We should tell him that, on the appearance of headache, neuralgia, ocular disturbances, troubles of speech, vertigo, unusual sleepiness or insomnia, transitory or trifling paralysis, tremors, fits, weakness or numbness of the legs, sexual excitement, or impairment or troubles with bladder or rectum, he should at once consult a physician, and call his attention particularly to the syphilitic history.

TWO CASES OF RENAL SURGERY.[1]

DOUBLE NEPHROTOMY: ON ONE SIDE FOR PYONEPHROSIS AND CALCULUS; ON THE OTHER, FOR ACUTE OBSTRUCTION OF THE URETER. NEPHRECTOMY FOR PYONEPHROTIC KIDNEY: IMPROVEMENT.

BY F. LANGE, M.D.,
OF NEW YORK.

CASE I.—About the middle of September of this year I was called in consultation by Dr. Neumer, of this city, to see a Mr. T., thirty years of age, who pretended to have suffered from urinary trouble since his twelfth year, to have had pus in his urine all the time since, which has become most abundant during the past three or four weeks, while at the same time pain and frequency of urinating have become intolerable. An examination under chloroform, which had to be administered on account of the excessive irritability of the patient, showed no stone in the bladder. A round, resistant, immovable tumor, about the size of the head of a newborn child, was felt in the region of the left kidney; the right kidney could likewise be distinctly felt, hence was dislocated downward, but did not seem to be enlarged to any considerable degree. The pain was located almost exclusively in the left side and in the pendulous portion of the penis. Urine contains a large quantity of pus. Microscopically, nothing but pus-cells, no blood, no cylinders.

Simple pyonephrosis on the left side was diagnosticated. The absence of blood in the urine, and of symptoms that might have pointed to an obstruction at any time, spoke against stone. The other kidney was apparently not healthy either; probably chronic pyelitis and interstitial nephritis existing there.

Simple nephrotomy on the left side was performed on the 2d of October. Lumbar longitudinal incision. In the region of the perinephritic fat a hard, resistant, fibrous mass was encountered, the wall of the pyonephrotic sac. After having cautiously penetrated through it I struck stone, and removed, after a tedious digging of about an hour and half, quite a considerable quantity of irregular shaded calculi, which apparently were scattered in all directions through the recesses of the calices. They were mostly, with their irregular edges, embedded so deep into the tissue that their removal was impossible without some bleeding and injury to the tissues. Mostly thin partition walls had to be broken by means of the finger and instruments in order to get at a new nest of stones. Though finally I did not feel any more stones, I had a moral conviction that there were more, but I desisted from further proceeding on account of the weakness of the patient. Drainage, frequent antiseptic irrigation with warm borosalicylic acid, small doses of morphia. The patient after about six weeks was discharged in a very much improved general condition. The pus from the urine had diminished very promptly, without disappearing entirely. The discharge from the now existing pyonephrotic fistula was moderate, apparently very little admixture of urine. The palpable tumor had considerably diminished in size.

Now comes the most interesting episode in the history of this remarkable case:

About the 25th of November the patient commenced to complain of pain in the abdomen. His bowels became obstinately constipated, and a few days later the urine was remarkably scanty. On the 28th the patient was reported to be very sick. Being unable to visit him on account of other engagements, I asked, in the absence of the family physician, another colleague to attend him, who sent me word that the man had general peritonitis. He had also tried to empty his bladder, because for almost twenty-four hours no urine had been passed, but had only withdrawn a few drops.

In seeing the patient on the morning of the 29th, I found the man with a tympanitic, very painful abdomen. The principal pain, however, was located in the right side, while the first operation had been done on the left. His pulse was weak, dyspnœa, beginning collapse; not a drop of urine in the bladder. I diagnosticated occlusion of the right ureter, and proceeded to operate at once, after the patient had been transferred to my institution. In first exploring the left side, because of the idea that eventually some inflammatory process might have proceeded across to the other side from the kidney originally operated upon, I again found stones, and after some searching removed a considerable quantity.

I then did lumbar incision on the right side, having placed the patient on his belly with slight inclination toward the side of the operation, as recommended by me before for exploratory incision of the pelvis of the kidney, found all the connective tissue under the quadratus lumborum infiltrated with watery fluid, resembling urinary infiltration; removed the fat from the rear aspect of the kidney and found in its substance, and quite near the insertion of the pelvis, an abscess, which seemed about to perforate. After opening it, I passed my finger without resistance into the pelvis and in withdrawing it a great quantity of bloody urine escaped. The pelvis was so much dilated that I was very well able to pass my finger into the first part of the ureter. Lower down, in introducing a slender, long, thin

[1] Read before the New York Surgical Society, Dec. 22, 1885.

bladed dressing forceps. I met with a resistance without having the touch of a stone. I then, by means of a large syringe, injected warm water in the direction of the ureter, when after a few injections this mass emerged; a whitish-gray plug, about the size of the end phalanx of the small finger, somewhat flattened and conical, resistant, but brittle, and apparently consisting of an old fibrinous clot into which watery substance and numerous gravel-like concretions were embedded. I then was able to pass a middle sized bougie directly down into the bladder without any resistance.

There was not inconsiderable venous hemorrhage, which, however, was easily checked by an iodoform gauze tampon after a middle-sized drainage tube had been inserted into the pelvis of the kidney.

On the first day after the operation three quarts of cloudy, slightly bloody urine had been discharged. Almost all the urine seemed to pass by the normal channel, and about one week after the operation the tube was removed. Several pieces of necrotic tissue passed at times with the urine, and in some of them, though they were entirely disintegrated, the outlines of glomeruli and urinary canaliculi could be detected. The patient's general condition has since remarkably improved, and though I do not have any sanguine hopes so far as complete recovery is concerned, I still think that the last operation has saved the patient from imminent destruction. He has now a superficial, healthy-looking, granulating wound on the right side, and a fistula discharging a moderate amount of pus on the left. The fact that during the occlusion of the right ureter no urine was found in the bladder, is conclusive proof that the left kidney has entirely lost its significance as a urine-secreting organ. I should not wonder if it contained still more calculi in some remote diverticulum of the cicatricial sac. The urine now passed has only a very moderate sediment of pus, its quantity is on an average three pints. Appetite very good. Evening temperature about 100°. Four weeks have passed since the operation.

Weight of stones removed, six drachms. About fifty pieces, varying in size from a pea to a hazelnut, besides hundreds of stone granules, consisting of oxalate and phosphate of lime, the latter predominating.

In the above case the presence of stone was a surprise to me, because at no time had there been any symptoms conclusively indicating stone.

In the following case stone had been diagnosticated both by me and by other physicians, while the operation taught us differently.

NEPHRECTOMY FOR PYONEPHROTIC KIDNEY: IMPROVEMENT.

Mrs. R., twenty-six years of age, married for a little more than three years and healthy, though somewhat delicate, until her present disease, gives a good family history. Menstruation appeared at her fifteenth year, and has always been regular except during two pregnancies in the first and second years of her married life. She dated her present disease from February, 1880, when, after a severe cold, bladder trouble set in, which was taken for and treated as cystitis, and became rather severe in the summer of the same year, at which time not infrequently a bloody discharge appeared with the urine, often in large clots and with free admixture of mucus. Gradually pain and discomfort became somewhat less without disappearing entirely. In 1881 the patient was treated by turpentine internally for about nine months. Besides that, she has taken all imaginable waters which are usually prescribed for these troubles. The patient was married in September, 1882, and became severely ill soon after, suffering excruciating pain until, after a protracted retention of urine, a large piece of flesh, as she says as large as a small fist, was discharged, and at last extracted from the bladder by herself, after which improvement of the general condition took place. Bloody admixture in urine, however, remained, which sometimes has been very free. Eleven months after marriage her first child was born. About twelve days later she commenced to suffer from severe pain in the lumbar region, which lasted for about three weeks, and was principally located, as the patient remembers, on her right side. Then followed a comparatively free interval until, about four months later. During the first four months of her second pregnancy similar pains set in, mostly in the right lumbar region, radiating toward the right knee. Often when she tried to get up after such an attack of pain, she had a feeling as though her legs were paralyzed, and as though she must raise them with her hands to put them into motion. Toward the end of her pregnancy she suffered again, less but very severely, also a short time after the delivery, when a similar attack to that after the first delivery occurred, and was of several weeks' duration. From January, 1885, until the following summer she was confined to bed, became gradually weaker, and was never without pain, while her urine was always more or less bloody and cloudy. During the months from July to October, during her stay in the country, she improved under liberal milk diet, to become worse again when she returned to the city. Throughout the last five years there seems never to have been normal function of the bladder, and never normal urine, almost always admixture of more or less blood, mucus, or pus. Her health has gradually failed, and when I saw her first in October, she presented in her extreme emaciation, nervousness, and irritability, a really miserable picture.

Under chloroform one was able to palpate both of her kidneys; they seemed to be about normal size, but were located a little lower down than normal. Examination of bladder negative. A moderate amount of sediment in the sometimes pale and watery at other times bloody urine. Microscopically, a great many epithelial cells from the bladder, pus, and red blood corpuscles. Specific gravity after about eight days of observation varying between 1011 and 1021. Quantity, a pint and a half to three pints. Once a piece of a granulated cylinder was detected. Very severe pain at intervals, located principally in the right lumbar region. Also dysuria. Patient reports that exercise markedly increases pain and amount of bloody admixture. At times pain is said to be quite intolerable. She also mentions that at

times, during severe attacks of pain, urine of more normal quality has been discharged.

Lumbar incision on the 26th of November, in belly posture. Ureter laid bare and opened. Difficulty in finding lumen, which seemed to be partly obliterated. A fine probe could be passed to the distance only of about one and a half inches. Pelvis of kidney hardly noticeable. Seems to have shrunk. Fatty tissue intimately adherent. Surface of kidney laid bare. The whole organ seems to be cystic. Some of the cysts punctured contain watery fluid, others a flocculent pus. The whole organ seeming degenerated and worthless, was removed. Adhesions on upper and lower end separated by actual cautery. Silk ligature in three portions around pedicle. Very insignificant loss of blood. No bad symptoms during or after the operation. After four weeks patient was discharged much relieved from pain and suffering; somewhat improved constitutionally. Urine with some change for the better, inasmuch as amount of pus and blood has been less, the latter for some time disappearing entirely. Bladder symptoms varying; as a whole, improved. There is no doubt that the remaining kidney is also in an abnormal condition, and the outlook for ultimate recovery is by no means flattering. At times the patient complains of a severe pain over the right iliac fossa and is extremely sensitive to pressure. From the condition of the ureter near the pelvis of the kidney. I should judge that an ulcerative process, leading to obliteration, must have taken place in its upper portion.

The removed kidney, which was of normal size and shape, shows almost no cortical substance, and consists of a large number of cystic cavities with smooth walls, mostly filled with pus, and varying in size from that of a hazlenut to that of a large walnut. Microscopically, the elements of the kidney are preserved in the remainder of cortical substance. I must say that the quality of the pus suggested to me that the nature of the process might be tubercular, though nowhere could cheesy deposits or infiltrations be found. I shall cause a more complete microscopical examination to be made.

MEDICAL PROGRESS.

Cutaneous Affections in Gonorrhœa.—In the *Revue de Médecine*, M. Gilbert Mallet invites renewed attention to the eruptions met with in the course of gonorrhœa. Carefully excluding all cutaneous eruptions that may be due to errors in diet or the administration of cubebs or copaiba, he classifies the remainder in three divisions: (1) Eruption closely resembling scarlet fever or measles; (2) rashes which may be described as those of "polymorphic erythema;" (3) purpuric patches. He produces evidence which suggests a probable relation of cause and effect between gonorrhœa and the eruptions of the first group. They come on, for the most part, late in the stage of the decline of gonorrhœa, last about twenty-four hours, and are followed by furfuraceous desquamation; they are often associated with severe gastro-intestinal disturbance, and can hardly, at first, be distinguished from the rash of measles or scarlatina. The second group is distinguished from the copaiba rash by (1) absence of the itching often present in that affection, (2) by the knotty appearance of the erythema, and (3) by the appearance of successive crops of eruption. The evidence in favor of the outbreak of purpuric patches does not seem so satisfactory. Some of the cases are probably those of peliosis rheumatica occurring in patients suffering from gonorrhœal arthritis. M. Mallet rejects the reflex and pyæmic theories of the origin of gonorrhœal rheumatism and the cutaneous manifestations, and argues strongly in favor of the absorption of a specific gonorrhœal virus.—*Weekly Medical Review*, December 26, 1885.

Therapeutic Uses of Sneezing.—The *St. Louis Medical and Surgical Journal* quotes Coiffier, who says in a recent work, "if an expectorant is indicated, and the remedy at hand fails to act as it should, provoke sneezing. A sneeze loosens up the air-passages, and sets the excretories into vigorous action. With children, a pinch of snuff is generally all-sufficient. With their elders, especially those in the habit of taking snuff, the poudre sternutatoire of the codex is better. Veratrine is a powerful provoker of sneezing—one one-hundredth part of a grain added to a half ounce (say 1:25,000) of snuff increases its sternutatory powers immensely. Again, there is nothing like a sneeze in expelling foreign bodies from the air-passages." M. Coiffier gave a number of incidents confirmatory of this axiom. In two instances where he failed to excite sternutation otherwise, he succeeded by conveying to the base of the nasal fossæ a minute portion of veratrine, scarcely the two-hundredth part of a milligramme, which he carried thither on the end of a sound.—*Medical Age*, Dec. 26, 1885.

Fatty Acids in Normal and Pathological Urine.—Jaksch, of Vienna, records the following results from recent experiments:

1. In normal urine traces of fatty acids are present.

2. In certain pathological conditions the fatty acids are present in relatively considerable amount. Thus, in the total renal excretion of twenty-four hours in fever patients, they are present to the extent of 0.06 gramme to 0.1 gramme, and in hepatogenous lipaciduria from 0.6 gramme to 1 gramme.

3. After the volatile fatty acids of the urine of febrile and hepatic diseases have been removed by oxidation, fatty acids still remain in the proportion found in normal urine; the acids so far found are formic, acetic, and butyric.—*Deutsche med. Woch.*, Dec. 10, 1885.

Ligation of Primitive Carotid Artery.—Dr. Arpal, of Saragossa, described the effect of a suicidal pistol wound behind the right ear, with a furious hemorrhage, necessitating the ligation of the primitive carotid artery of the same side. This was done, an antiseptic dressing applied, and thirty-one days after the operation he was discharged cured, and has for two months pursued his vocation without inconvenience.—*Gaz. Hebdom. des Sciences Méd.*, Dec. 12, 1885.

Extirpation of the Spleen in Leukæmia.—Rydygier records the removal of a six pound spleen from

a leukæmic woman, aged thirty-one, who died, on the following morning, of hemorrhage from the abdominal wound. The ligatures on the main bloodvessels involved held perfectly, and Rydygier ascribes the secondary hemorrhage to imperfect coagulation dependent upon the condition of the blood. This case brings the total number of deaths from this operation up to eighteen, of which sixteen were from hemorrhage and two from shock. Thus far, the only successful case of splenic extirpation for leukæmia is that performed by Franzolini.—*Centralb. f. d. med. Wiss.*, Nov. 21, 1885.

Tartar Emetic in Phthisis.—Bucquon records the successful employment of tartar emetic in many cases of phthisis. He administers the drug at first in the aggregate daily dose of one and a half to two grains, the patient at the same time not being allowed to use fluid, in order that vomiting may be avoided. When tolerance is established, the aggregate daily dose is reduced to three-quarters of a grain, which, he states, to reduce fever, cough, and expectoration, increase the appetite, and induce a tendency to constipation. The only contra-indications for the treatment described, are severe diarrhœa and persistent intestinal ulceration.—*Centralb. f. klin. Med.*, Nov. 28, 1885.

Injections of Charcoal Water in Typhoid Fever.—As a method of partially disinfecting the intestinal contents of typhoid patients, and thereby not only rendering the stools inoffensive but also diminishing the danger of auto-infection, Duval strongly recommends the use of injections of charcoal water. A soupspoonful of poplar charcoal is well mixed with each injection, which is repeated from two to three times daily. A case is cited in which the use of this absorbent rendered the intensely repulsive dejecta absolutely inodorous, and in which great meteorism was immediately diminished and finally disappeared.—*L'Abeille Médicale*, Dec. 21, 1885.

The Ferment of Sputa.—The observations of Filehne, who found in the sputa of pulmonary gangrene a ferment capable of dissolving albumen and elastin, have been extended by Escherich, with the following results:

The glycerine extract of the sputa of pulmonary gangrene dissolved albumen rapidly in alkaline solution, but was inactive in acid media. Serous, muco-serous, and muco-purulent sputa of bronchitic origin, were practically inactive. The sputa of phthisis gave positive results in the fifteen cases in which it was used, though its proteolytic power was somewhat less than that manifested by the sputa of gangrene of the lung. The action of bacteria as a digestive agent was excluded by control experiments.—*Centralb. f. klin. Med.*, Nov. 28, 1885.

New Antiseptic Dressing for Use in the Field.—Desquin has recommended a very compact, simple, and cheap antiseptic dressing for use in the battlefield. It consists of filter-paper, sterilized by a prolonged heat of 248° F., which is then immersed in any desired antiseptic solution, and slowly dried. Seven or eight layers are applied to the wound, covered with gutta-percha, and held in place by a few turns of roller-bandage.—*Revue de Thérapeutique*, December 15, 1885.

Passage of Pathogenic Microbes from Mother to Fœtus, and in the Milk.—Kubassow (*Wratch*, 1885, Nos. 31, 32, and 36), after passing in review the observations of Chamberlain, who proved the passage of microbes from mother to fœtus in chicken cholera, publishes an important original investigation from the laboratory of Pasteur.

He has shown that in pigs, malignant œdema rouget (a disease of swine), and tuberculosis, the microbes concerned pass to the fœtus, a transit which he ascribes to direct communication between the vessels of the fœtal and maternal placentæ (?). In the so-called Siberian pest, rouget, and tuberculosis, the bacilli pass to the milk, where they are to be found up to the death of the animal or the cessation of the secretion. In the absence of any wound, especially of the alimentary tract, the sucklings are apparently uninfected by such milk, even up to the death of the mother. Sows affected with tuberculosis or rouget did not become pregnant.—*Centralb. f. Gynäkologie*, Dec. 5, 1885.

Cocaine in the Treatment of Diseases of the Nose, Larynx, and Pharynx.—Schnitzler records one hundred cases in which he has employed cocaine in the treatment of diseases of the upper air-passages. He regards its use as satisfactory in operations upon the tonsils, also in hyperæsthesia of the pharynx, but as not especially advantageous in acute pharyngitis. While praising the application of the drug in operations upon the larynx, he regards its use as superfluous in laryngoscopic and rhinoscopic examinations. In irritative cough, in acute and chronic laryngeal catarrh, and in laryngeal tuberculosis, the symptoms were favorably affected by the treatment in question.

He regards the presence of glycerine as advantageous, and recommends the following formula as adapted for general use:

Cocaine muriate	2-5 parts.
Glycerine	20 "
Water	80 "

When a long-continued anæsthetic effect is desired, the following formula is recommended:

Cocaine muriate	2-5 parts.
Morphia	2 "
Glycerine, Water,	of each 50 "

For insufflation:

Cocaine muriate	2-5 parts.
Lead acetate	20 "
White sugar	80 "

Or:

Cocaine muriate	2-5 parts.
Bismuth subnitrate, White sugar	of each 50 "

For nasal injections and for inhalations a solution of cocaine of the strength of one part in five hundred is employed.—*Centralblatt f. Chirurgie*, Dec. 19, 1885.

The Respective Toxicity of the Organic and Saline Constituents of the Urine.—After passing in review the observations of Felz and Ritter, who regarded the symptoms of experimentally induced uræmia as due to the inorganic urinary constituents, especially the salts of potash, and also those of Bouchard, who

affirmed the toxicity of the organic elements, LÉPINE and AUBERT record the results of their experiments in this regard.

In each of their experiments two dogs of the same race and of equal weight were used. Into the femoral vein of one of them was injected a given quantity of normal urine, while into the same vein of the other dog there was injected a watery extract of the *ash* of the same urine, diluted to its previous volume. The results showed that for each kilogramme of the dog's weight 60 c.cm. of normal urine were required to induce death, while 65 c.cm. of the aqueous extract of the urinary ash per kilogramme of body-weight were needed to produce death. The toxicity of the normal urine, therefore, exceeds but slightly that of its inorganic constituents. The case was different when the urine of fever patients was used. Here 25 c.cm. per kilogramme were sufficient to cause death, while of the solution of its inorganic constituents, prepared as before, 40 c.cm were found to be the minimum lethal dose. It is evident, therefore, that the urine of fever possesses nearly twice the toxicity accounted for by its inorganic constituents. The symptoms in the two groups of cases also were different, for while the urine of fever caused clonic convulsions, the normal urine always produced death by heart failure.—*Centralbl. f. klin. Med.*, December 19, 1885.

MITRAL STENOSIS AND LEAD POISONING.—The influence of saturnine intoxication on the various tissues of the body is a subject that merits even further attention than it has yet received. Neurologists are acquainted with a variety of nervous diseases clearly the outcome of lead poisoning; and Dr. Gowers has, we believe, asserted that no symptom of nervous disease may not be due to lead. Vascular lesions have long been known to be caused by the prolonged action of this metal; and now M. Duroziez suggests that a limited lesion of the heart—mitral stenosis—may in a certain number of cases be due to the same far-reaching cause. The suggestion arises from his having observed several cases of mitral obstruction in house-painters, compositors, and certain polishers.—*Lancet*, January 2, 1886.

THE ACID REACTION OF GONORRHŒAL PUS.—MARTINEAU maintains that the pus of gonorrhœa always presents an acid reaction, and that this characteristic affords a valuable diagnostic sign. Thus, while the local secretions in simple vaginitis and vulvitis are alkaline, these diseases, when of gonorrhœal origin, present an acid secretion. The same condition obtains in urethritis in the male, and also in the relatively very rare condition of gonorrhœal metritis, which, according to Martineau, may be diagnosticated by the introduction of litmus paper into the uterine cavity.—*Centralb. f. Gynecologie*, December 19, 1885.

LACERATION OF THE OS AND CERVIX UTERI, AND THE OPERATION OF TRACHELORRHAPHY.—DR. GRAILY HEWITT, in a clinical lecture which is published in the *British Medical Journal* for Jan. 2, 1886, summarizes his views as to the indications for the performance of trachelorrhaphy as follows:

The operation is indicated by the presence of a chronic extensive eversion of the cervical lining, by the presence of considerable hypertrophy of the os, the result of laceration, and the more so if hypertrophy and eversion be conjoined; by the presence of chronic severe local pain, evidently traceable to the irritation of a raw surface less extensive in amount, or traceable to cicatricial hardening at the bottom of the fissure; by the association of marked laceration with a troublesome displacement of the body of the uterus; by the presence of repeated miscarriages in a chronic case; by the presence of a severe recent laceration, even in cases where no severe symptoms have had time to develop themselves, with the view of preventing (1) cellulitis; (2) the occurrence of cancer; (3) the supervention of symptoms generally; lastly, by the presence of general severe prostration, inability for locomotion, etc., obviously traceable to laceration.

The operation itself is not, in most cases, a difficult one, but, in some cases, it is so. In assisting to hold the cervix down, he has found the large tenaculum hooked forceps, depicted in the last edition of his work on *Diseases of Women*, made by Mayer and Meltzer, of very great utility. Sometimes the nodular hypertrophy renders coaptation of the edges, after paring them, not easy, owing to one side of the rent being very short, the other very long. Another difficulty is, in some cases, the excessive hardness of the tissues to be perforated by the needle, which is sometimes so great that much force is required to penetrate the tissues. The needles need to be very strong for such cases. He has found No. 6 silver wire most suitable for sutures, and has generally removed them in not less than ten days. Probably it would be better to leave them a week or two longer, in cases where the patient is very weak and nutritive action feeble. The importance of a preparatory treatment before proceeding to the operation is emphasized.

TWO CASES OF SEVERE ANÆMIA CURED BY SUBCUTANEOUS INJECTIONS OF BLOOD.—Two severe cases of anæmia have been treated by SILBERMANN by v. Ziemssen's method. One case was that of a very anæmic boy eight years of age, who suffered with somnolency and frequent fainting. With great caution twenty c.cm. of defibrinated blood were injected under the skin of each thigh, which procedure was repeated nine days thereafter. Improvement dated from the first injection, and was constant for ten weeks, when patient was discharged cured. In the second case a girl of eleven years, who had presented symptoms of the most intense anæmia, resulting from intestinal hemorrhage, received twenty-five c.cm. of blood in the subcutaneous connective tissue of each thigh. Her gain in weight was steady from this time and amounted to nearly eight pounds in six weeks.—*Centralbl. f. klin. med.*, Dec. 5, 1885.

LEFT VENTRICLE PERFORATED BY A GASTRIC ULCER.—At a recent meeting of the Academy of Medicine in Ireland, a very remarkable specimen was exhibited by DR. J. MAGEE FINNY. It was an example of an ulcer of the stomach, which perforated the left ventricle of the heart and caused death by hemorrhage. The subject of this interesting example was a lad aged seventeen, of a somewhat strumous constitution, who was admitted into hospital under Dr. Finny's care about two months since, and died early in December. During his stay in the hospital, pain was complained of about the cardiac region, and pericarditis was diagnosed, but,

strange to relate, there were no symptoms of any gastric irritation, neither pain nor vomiting. On the day death occurred the patient passed blood by stool, and a post-mortem examination showed that the stomach was entirely filled with blood.—*Lancet*, December 26, 1885.

Trephining for Epilepsy.—At a late meeting of the Northumberland and Durham Medical Society, Dr. Oliver showed a boy who had been trephined in the right parietal region for supposed traumatic epilepsy. The fits had developed after a blow on the head; and although, on admission to the Newcastle-on-Tyne Infirmary, no injury could be detected, it was decided to trephine, as the epileptic phenomena were unilateral. The opening was made an inch above and behind the right ear, and a quantity of effused serum and lymph removed. The wound healed well, but the fits continued, though with less severity and frequency.—*British Medical Journal*, January 2, 1886.

Alopecia Areata and Bacterium Decalvans.—V. Sehle has described a micrococcus found in the hair roots in alopecia areata, and has succeeded in obtaining a pure culture of the organism and also in producing the characteristic local baldness in certain animals by its inoculation. It is probable that the micrococcus of v. Sehle is identical with the organism described by George Thinn in 1881.—*Centralb. f. klin. Med.*, December 5, 1885.

Brown-Séquard's Mixture for Epilepsy.—

Iodide of potassium	8 parts.
Bromide of potassium . . .	8 "
Bromide of ammonium . . .	4 "
Bicarbonate of potassium . . .	5 "
Infusion of calumba . . .	360 "

Dissolve. A teaspoonful before each of the three principal meals, and three dessertspoonfuls on going to bed. The solution should be given diluted in cases of idiopathic epilepsy.

If the pulse of the patient be feeble, the potassium bicarbonate is replaced by ammonium carbonate, while for the 360 parts of infusion of calumba there are substituted 90 parts tincture of calumba and 270 parts of distilled water.—*L'Union Médicale*, December 31, 1885.

Muscle Tonus.—Mommsen has repeated, with certain modifications, the experiments of Brondgeest, which showed that in a suspended decapitated frog, the leg in which the sciatic nerve was cut, hung lower than did the other leg—in other words, possessed less tone. Mommsen concludes that muscle tonus is a muscle reflex in the broadest sense of the term, and that its stimulus is a mechanical one, namely, the constant stretching of the muscle and its adnexa, as conditioned by its anatomical attachments. The reflex is not exclusively dependent upon the stimulation of cutaneous sensory nerves, for flaying, section of the posterior spinal roots, and anæsthesia of the skin (by carbolic acid) do not destroy the tonus.—*Centralb. f. klin. Med.*, December 5, 1885.

Emulsifying Power of Human Pancreatic Juice.—Ch. Robin obtained from each of two executed criminals, at respectively 8 and 12 hours after death, a pancreatic extract of marked emulsifying power. Emulsions made with these extracts remained during one month entirely without change and without the appearance of decomposition. The emulsion produced by the bile in these cases was not permanent.—*Centralb. f. d. med. Wissenschaft*, December 26, 1885.

Trephining for Traumatic Epilepsy.—Mr. Whitehead presented at a recent meeting of the Manchester Medical Society a man, aged twenty-eight, whom he had successfully trephined for traumatic epilepsy. The patient fell down a quarry, a distance of thirty feet, in May, 1884, and received a compound fracture of the skull, for which he was treated for seven weeks in the Bradford Infirmary. Since his discharge, he had suffered from constant headache, and for seven weeks preceeding his admission into the Manchester Infirmary on September 29, 1885, he suffered from epileptic fits, sometimes amounting to six during twenty-four hours, and never free from headache and depression during the intervals. On October 2d, he was trephined immediately outside the area of the fracture. Nothing abnormal was observed through the aperture; nevertheless, the man had ever since, with the exception of one attack, been free from fits, and his headache and depression had disappeared. Mr. Whitehead attributed the improvement rather to reflex influences than to any direct result of the operation. He promised to report the further progress of the case.—*British Med. Journal*, January 2, 1886.

Further Researches on Malaria.—In the current number of the *Fortschritte der Medicin* there appears a translation from the Italian of some further researches on malaria by Prof. Marchiafava and Dr. Celli. The chief results so far obtained are thus summed up: 1. In the blood of individuals suffering from malaria there may be found in the interior of the red blood-disks minute organisms composed of homogeneous protoplasmic particles which are endowed with lively amœboid movements, and can be distinctly stained. These organisms are only found in the blood in cases of malaria, and are termed plasmodes or hæmoplasmodes of malaria. 2. In the interior of these units reddish or black pigment may be detected, but it is not an essential constituent, being merely derived from the hæmoglobin of the red disk. According as this pigmentation does or does not take place, we have or have not melanæmia. 3. The hæmoplasmodes may be transformed by a process of fission into a group of granules which do not possess amœboid movements. This fission may occur in the pigmented as well as in the non-pigmented plasmodes, and it is most probable that this is the ordinary mode of multiplication within the human organism. Infection may occur as the result of the intravenous injection of malarial blood, as is shown not only by clinical experience, but also by the fact that in the blood of the receiver the hæmoplasmodes may be discovered. The units further increase as infection progresses, and diminish, until they disappear, as infection ceases, whether naturally or under specific treatment. The authors, in determining some of the latter points, made experiments on a man aged forty-three, who was suffering from paralysis agitans, but who had never had any malarial fever. The blood was taken from a malarial subject during his apyrexial period, and the febrile movement commenced in the receiver the same evening.—*Lancet*, January 2, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 16, 1886.

INFANTILE PARALYSIS OF CEREBRAL ORIGIN.

PARALYSIS in children, even when unilateral, is usually regarded as a spinal affection, but there are, apparently, certain cases of cerebral origin in which the motor area of the gray cortex is involved, resulting in the production of paralysis, more or less complete, on the opposite side of the body. STRÜMPELL describes this form under the term polioencephalitis acuta, and from his account in the *Deutsche medicinische Wochenschrift*, x. 44, and from the more recent paper of RANKE, in the *Jahrbuch für Kinderheilkunde*, xxiv. 1 and 2, we can gather a tolerably accurate picture of the disease.

Strümpell has had twenty-four cases, the youngest in an infant of six weeks, the oldest in a child of six years. In a majority of the cases no special cause was apparent, but one followed measles, and another scarlet fever. As in poliomyelitis, healthy children seem most frequently attacked. There is usually an initial stage of fever, with vomiting, convulsions, and sometimes loss of consciousness. Occasionally the attack comes on suddenly without any premonitory symptoms. After two or three days the parents notice that the child has lost the power of the muscles on one side of the body. There is more often total paralysis of the arm than of the leg; and the facial paralysis is seldom extensive, but is confined to the lower region, and is of slight duration. There may be monoplegia, either brachio-facial or crural. In some cases there is no definite paralysis, but rather an ataxia, with great clumsiness in using the affected members. The muscles do not undergo a degenerative atrophy, nor do they present the reaction of degeneration. The normal tension may be maintained, and the flaccid condition of poliomyelitis is not observed. The reflexes are usually increased. Sensation on the affected side may be reduced, but it is more commonly normal. Ultimately, as a result of the cerebral irritation, there may be epileptic attacks, hemichorea, athetosis, contractures, and, if the affection is in the left hemisphere, disturbances of speech.

Strümpell draws a parallel between the cerebral and the spinal affection. In both, healthy children are attacked after an initial period of fever, and in both the gray matter is the seat of the disease, the anterior horns of the cord being affected in poliomyelitis, and the motor area of the cerebral cortex in polioencephalitis.

In the later stages of the disease there is atrophy of the affected convolutions, and the shrinkage may be so great as to induce the porencephalous condition described by Kundrat. The precise nature of the changes in the early stage has not yet been determined.

Ranke records nine cases which correspond, more or less closely, with Strümpell's description; six became hemiplegic, and three monoplegic. In the former there were irregular choreic movements in the affected limbs. Unlike the condition in poliomyelitis, the tendon reflexes were retained. The electrical conditions of nerve and muscles were not diminished, and there was no reaction of degeneration.

This condition of polioencephalitis acuta described by Strümpell would seem, in the majority of instances, at least, to be simply the early stage of the affection known as spastic hemiplegia of infants, so well observed by James Ross, Charcot, and others. In these cases the onset of the disease is in early life, from the age of two months to four or five years. As described by Ross in *Brain*, vol. v., the attacks come on with convulsions and unconsciousness, often preceded by a brief initial illness, and when the child recovers consciousness, the hemiplegia is noticed. Subsequently contractures become established in the affected limbs, which are often the seat of athetosis and choreic movements. Later on, at the tenth or twelfth year, epileptic attacks supervene, and there is failure of the intellectual faculties. The lesion is essentially a diffuse sclerosis, with retraction in the motor area of one cortex, and this is sometimes so marked that the cases have been described as unilateral atrophy of the brain. Among possible causes of the primary lesion, Ross suggested a local encephalitis.

The subject of spastic hemiplegia is exhaustively considered in a recent number of Virchow's *Archiv*, Bd. cii., by BERNHARDT, who records eighteen cases, occurring in early childhood. Healthy children were usually attacked, but in three or four instances the disease came on during convalescence from in-

fectious diseases. As in Strümpell's cases, convulsions and loss of consciousness were the early symptoms, and then hemiplegia, more or less complete, followed, in time, by a spastic condition, choreiform movements, and epileptic attacks.

Bernhardt doubts whether the initial lesion in all instances is the same; but, however that may be, he holds that we can recognize an important clinical group of cases, the primary symptoms of which are characterized by convulsions, loss of consciousness, and hemiplegia, and the secondary by contractures, hemichorea, athetosis, psychical anomalies, and epileptic seizures. The anatomical condition is an atrophic sclerosis, more or less extensive, of the motor region of one hemisphere, and it is very probable that a considerable proportion of these cases have their origin in the polioencephalitis acuta, so well described by Strümpell.

The post-mortem appearances of the acute stage, which are needed to complete the evidence, will doubtless soon be forthcoming.

STRAW IN STREET CARS.

EVERY winter the complaint is renewed against the use of straw or hay upon the floors of the street passenger railway cars. Observation and experience have shown the practice to be uncleanly and injurious to health. It would seem that clean, fresh straw or hay, frequently renewed each day, with a sweeping of the floor before such renewal, would conduce to the comfort of the travelling public during the winter season: but such careful regulation is the rare exception, not the rule. A mass of straw is made to do service for the entire day, or still longer, its continued use permitting of its defilement by the tracking of dirt from the streets, by the expectorations from the lungs, by saliva often stained with tobacco, and by the absorption of exhalations from the body and lungs, especially if the straw be damp. A portion of the straw is pulverized under the feet of hundreds of passengers, and gives rise to a fine dust of a heterogeneous composition, which is not only an irritant to the air passages, but may also be injurious according to the nature of the impurities which it contains. In brief, the straw becomes the receptacle for all kinds of impurities which are imparted to the confined atmosphere of the cars, rendering its condition noxious. The custom is a pernicious one, and should be interdicted.

The Board of Health of Philadelphia has condemned the practice as contravening the laws of health, and, in the absence of specific law on the subject, has requested its discontinuance. But as the street railway corporations are a law unto themselves, the request has been ignored. A movement is now on foot in City Councils to compel, by ordinance, the abandonment of the practice, and this movement is endorsed by the health board. Such an ordinance should receive the hearty support of the representatives of the people.

It is obligatory upon the street passenger railway companies to keep their cars always in the cleanest possible condition; and this requirement is especially important in the winter season, when free ventilation is cut off. Cocoa mats upon the car floors, changed frequently during the day, will answer the purposes of comfort and cleanliness. Their cleansing by scrubbing under a stream of water, and drying in a hot-air chamber, would be a matter of expenditure of trifling consideration compared with the advantages which would inure to the patrons of the companies from a condition of cleanliness constantly maintained. A word to the wise is sufficient.

HÆMOGLOBINURIA.

EVIDENCE is accumulating in favor of the view that hæmoglobinuria is a blood disease, and not primarily an affection of the kidneys. Certain toxic agents, of which malarial poison is the most clearly recognized, act upon the blood in such a way as to cause a separation of the hæmoglobin, which is then excreted, as a foreign body, with the urine, either alone or with the remnants of the disintegrated corpuscles. Many of the cases of the so-called paroxysmal hæmaturia are of this nature.

Experimental researches, particularly those of Afanassiew, in Cohnheim's laboratory, have clearly shown that various substances, such as glycerine, pyrogallic acid, and foreign blood, introduced into the circulation will cause destruction of the corpuscles. The dissolved hæmoglobin is excreted by the kidneys, and, if the dose of the poison is large, and the destruction of the corpuscles very great, jaundice may be produced as well as the hæmaturia. Nephritis of an intense character is an almost invariable consequence.

In cases occurring spontaneously in man and animals, evidence of blood destruction is, of course, afforded by the presence of the coloring matter in the urine, but there are surprisingly few observations upon the state of the blood itself during the attack. Some writers, indeed, speak of a granular débris in the plasma and a distorted state of the corpuscles, but we know of no observation similar to the one recorded by HEINEMANN, of Vera Cruz, in the current number of Virchow's *Archiv*, cii. 3; The case was one of hæmaturia in intermittent fever, occurring in a lad, aged fifteen, who when first seen had had quotidian ague for three days. Ever since a previous attack, three months before, the urine had been dark in color. During a paroxysm, while the temperature was 40.5° C., blood was drawn with a cupping glass and carefully examined. The red corpuscles had uniformly lost their coloring matter, which was in

solution in the plasma, so that the cells were represented by pale, colorless disks floating in a tinged medium. Scarcely a normal corpuscle could be found. After two days, the condition had so far improved that the corpuscles again presented a normal appearance.

Dr. Heinemann writes like a careful, well-trained physician, and the editorial supervision of the *Archiv für Pathologische Anatomie* is notoriously stringent, otherwise we should be inclined to doubt the accuracy of an observation which necessitates the conclusion that the oxidizing processes of the body may be carried on by hæmoglobin in a state of solution in the blood plasma. And further, as we cannot suppose that corpuscles which have once lost their coloring matter can ever be restored to the normal state, we must infer, in this case, a complete restitution of the cells within forty-eight hours, which seems scarcely credible. The observation, however, is of interest, and may serve to stimulate others who have cases of this kind to make a careful examination of the blood with a view of determining whether a solution of the coloring matter in the plasma, hæmoglobinæmia, always precedes the hæmoglobinuria.

There is a common affection of the horse, variously known as azoturia and acute nephritis, but which is probably, as Bollinger suggested, a toxic hæmoglobinuria, a careful study of which will, we feel sure, throw light upon the pathology of the subject in question. An animal, after standing for a day or two in the stable, is taken out for work or exercise, and within a short time is seized with weakness, particularly of the hind legs, breaks into a profuse sweat, and passes bloody urine. Death may take place within an hour, but, more commonly, the attack is prolonged for several days and recovery frequently occurs. The post-mortem appearances are largely those of acute nephritis and have been carefully described by A. W. Clement in the *Journal of Comparative Medicine*, October, 1885. There are also parenchymatous changes in the liver and in the muscles, particularly those of the lumbar region. The sudden onset, in apparently healthy animals, the rapidity with which the fatal termination may occur, the constant presence of hæmoglobin, with or without corpuscles, in the urine, together with the renal and other changes, make up a remarkable group and point to some quickly acting toxic agent as the cause of the disease. In certain anatomical features it presents a striking resemblance to many of the experimental cases described by Afanassiew, and a fuller knowledge of its pathology may lead to a better understanding of some of the examples of næmoglobinuria in man which are at present so puzzling.

ANOTHER EXPRESSION OF PROFESSIONAL SENTIMENT.

THE profession of Philadelphia, in the course of their loyal duty to the American Medical Association, have formally and most emphatically placed the seal of condemnation upon the men who have been giving support to the dissensions which were aroused at New Orleans, and which are tending to the destruction of the Association.

At the annual meeting of the Philadelphia County Medical Society, held last week, unusual interest centred around the election of delegates to the Association, and two tickets were placed in the field. One was framed in the interests of the supporters of the action of the Association at New Orleans in reference to the organization of the International Medical Congress, and included the names of all the men in Philadelphia who are prominently identified with this movement. The other was made up of nominees who are opposed to this action and the dissensions it has engendered in the profession. Both tickets were duly mailed in advance of the meeting to every member of the Society, so as to secure an absolutely free and fair, as well as full expression of opinion by the profession of Philadelphia. The latter ticket was elected by the overwhelming majority of more than four-fifths (169 to 36), at the largest meeting of the Society ever held.

It is the solemn duty of the New Committee of the Association charged with the arrangements for the meeting of the International Medical Congress at Washington, to ponder well, before it is too late, the meaning of this, and of the numerous other expressions of dissent which have reached them from all sides. They must know that the profession of Philadelphia, New York, Boston, Baltimore, Washington, and Cincinnati are practically united in disapproval of the action which brought the New Committee into existence, that serious differences of opinion, to say the least, exist in all the other principal cities of the United States, and that the sympathies of the profession of Canada and of Europe are not with them. They must recognize that to persist in their present course is to impair the good name of the American medical profession, and to imperil the vital interests of the American Medical Association.

One month ago THE MEDICAL NEWS, in an earnest plea for the restoration of harmony in the profession, expressed the hope that the Committee of the Association would use their influence to this end, and by their action show that in view of the present strained relations—which, if maintained, mean failure to the Congress and disaster to the Association—they were ready to sink personal considerations for the general good. We renew this plea to-day in the name of the large mass of the profession of the United States, who earnestly demand the restoration of harmony

and the preservation of the integrity of the American Medical Association. A crushing responsibility will rest upon the Committee if they fail to meet this demand.

REVIEWS.

A Complete Pronouncing Medical Dictionary. By Joseph Thomas, M.D., LL.D. 8vo. pp. 844. Philadelphia: The J. B. Lippincott Company.

A remarkably handsome book, with good paper, large type, and not unwieldy bulk. The system of pronunciation is that which characterizes other works by the same author, well and elaborately explained in the preface. Dr. Thomas also explains that he has thought it well to include many botanical terms on account of the close alliance existing between medicine and botany; but we were not prepared for the immense number of such terms with which each page bristles. Of course, where so much attention is devoted to the language of a collateral science, there is a lack of space for distinctively medical terms, always numerous and ever-growing, and the absence of very many of which terms detracts most seriously from the value of the book as a medical dictionary.

We will try to make clear our meaning by facts culled from a single page. We looked for pelyometer, an old term for pelvimeter, but Dr. Thomas has either not heard of it or thinks it unworthy of mention. The same thing is true of the synonymous word pelycometer. We look further, but alas! in vain, for that choice term pelycochirometresis. Now, it may be said, such terms are obsolete, and are barbarous; but, if the student of medicine comes across one of them, he will very naturally and properly look for an explanation of them in the pages of a medical dictionary. We take it that one of the important functions of a dictionary is to give information concerning words but rarely used, and we are most decidedly of the opinion that the medical student is more likely to require information about such old polysyllables than he is to be told all about the familiar family of plants known as Pelargoniums. The latter may supply his bouquets during his medical juvenescence, and may help to adorn him at his graduation; but, after that, if he practises obstetrics, he will find pelycochirometresis of far more importance to him than the whole family of Geraniums, even if one of these has been experimented with in medicine.

How complete the work is as a botanical dictionary we know not, that is beyond our province; but, should it possess the same defects in that direction as we have referred to from a medical standpoint, it will not be highly valued by students of botany. But it makes no pretensions in that direction, and any criticism at the hands of botanists would, therefore, be out of place.

A very noticeable article, and one which it would be unpardonable to pass by, is from the pen of Dr. Morris Longstreth, on Pathogenesis. It is thoroughly and admirably done, representing very fully the present state of our knowledge upon this important topic. We deem it as particularly incumbent upon us to mention this exhaustive paper, that we may help to disinter it from its surroundings, it being of a scope and character altogether unusual for any dictionary article, and different from anything we have noticed in its environment.

We have, perhaps, now said sufficient to give our readers an idea of the character of this *complete* dictionary. If there is anything we dislike, it is the utterance of harsh criticisms. If there is anything we like, it is to say smooth and pleasant things. We shall, therefore, withhold our hand, and content ourselves by remarking that we should have had even less to say had it not been for the extraordinary statement of the title-page, that the book is a *complete dictionary*. A dictionary it may be—indeed, we cannot deny that a dictionary it is; but, to term it a complete one, is to put black for white, and to speak of that which is not, as though it were.

Physicians' Visiting List for 1886. Lindsay & Blakiston, 1886.

This standard physician's note-book, now in the thirty-fifth year of its publication, is admirable both in its practical arrangement and mechanical finish. It is too well and favorably known to require description or praise.

Plumbing Problems; or, Questions, Answers, and Descriptions relating to House Drainage and Plumbing, from the *Sanitary Engineer*. With one hundred and forty-six illustrations. 8vo. pp. xiv. 244. New York: *The Sanitary Engineer*, 1885.

It has been a prominent feature of *The Sanitary Engineer*, a paper published weekly, and devoted to engineering, architecture, construction, and sanitation, to solicit queries on topics connected with the sanitary arrangements of dwellings and buildings generally, which are printed in its pages, with appropriate comments by persons specially fitted to discuss the various problems involved. The present volume is a selection from its pages of questions and comments illustrative of the common defects in house-drainage, plumbing, etc., as well as of the methods of their correction.

The illustrative cases relate to a great variety of subjects, and are included under the general topics of water supply, sewerage, sewage disposal, ventilation, heating, lighting, house-drainage, and plumbing. Appended to the book is a form of plumbing specification for an isolated country-house, and also the text of the plumbing laws and regulations in force in New York, Brooklyn, and Boston, in May, 1885, which will be most serviceable, as models, to those cities and towns which are contemplating the introduction of such regulations.

The book reminds one of Mr. Pridgin Teale's *Dangers to Health, or Pictorial Guide to Sanitary Defects;* but it is very much more comprehensive. Illustrations are freely used, but they are not the exclusive, though a very prominent, feature of the book. The drawings in many cases so plainly indicate at a glance the idea intended to be conveyed, that comment is unnecessary.

Most of the inquiries contained in the book have been suggested by actual experience, and have a bearing on practical questions of frequent recurrence. The answers and comments furnish a fund of information, pointedly detailed and intensely practical. As this matter is scattered through the pages of the different volumes of *The Sanitary Engineer*, it is available only to the few, and then only after diligent search. The selection of the

best material and its compilation in the present volume, is a thoughtful and most useful enterprise, which ought to be appreciated by the householder as well as by the artisan and professional sanitary engineer.

The book is well printed on good paper, is profusely illustrated, and as it is supplied with a good index and a full table of contents, it will be exceedingly useful as a work of reference, and will aid in solving many a troublesome problem.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, December 22, 1885.

THE PRESIDENT, CHARLES MCBURNEY, M.D., IN THE CHAIR.

DR. C. K. BRIDDON presented a patient with the following history of

PENETRATING WOUND OF RECTUM AND BLADDER; RECTO-VESICAL FISTULA, COMPLICATED WITH STONE; OPERATION; CURE.

J. Van Tassel, aged twenty-two years, native of United States, single, laborer. Entered Presbyterian Hospital in the city of New York, service of Dr. Briddon, Nov. 4, 1885.

Two years before admission, while driving, he fell on one of the "stakes" of a "bark rigging." The stake was blunt, about one inch in diameter, and six inches in length. It entered just behind the anus, penetrating nearly its whole length. When he raised himself from the stake there was a gush of urine, but very little blood. He did not suffer much pain, and went on with his team until exhausted, when he was taken home in a sleigh. During the following night, gas and feces were passed by the urethra. The external wound healed in four or five weeks, but the other symptoms continued. At times he would pass all his urine through the natural outlet, but nearly always the larger portion of it came by the rectum. Seven months before admission he began to suffer more pain in the perineum. Occasionally the stream would suddenly cease, and the suffering was aggravated by locomotion. On admission the patient's general condition was fair; he complained mainly of difficulty in urination; he had evening exacerbations of temperature, that were not influenced by quinine. A No. 27 French sound introduced into the bladder, came in contact with a stone of considerable size. Examination by the rectum found a fistulous communication with the bladder, situate a little to the left of the median line, and two inches and a half above the verge of the anus. He passed about sixty ounces of urine daily, the largest amount passed by the urethra in twenty-four hours being four ounces.

Operation Nov. 14, 1885, 3 P.M. Patient etherized and on his back. A catheter communicating with an irrigator was introduced into the bladder, and the cavity was thoroughly washed out with a warm solution of boracic acid. Its exit from the rectum was facilitated by the introduction of an anal speculum. The catheter was then withdrawn, and a staff was introduced and placed in contact with the stone. The patient was then placed in the knee-elbow position, with the pelvis a little higher than the shoulders, and the thighs secured in a position of abduction by an interfemoral crutch; the posterior wall of the anal aperture was transfixed by stout silk loops; and, whilst the parts were made tense by these, the posterior wall of the rectum was split in the median line as high as the point of the coccyx, aided by the introduction of a large Sims speculum and lateral retractors. It was possible to make a satisfactory digital and ocular exploration of the fistulous communication between the bladder and the rectum. It was distant two and a half inches from the anus. It admitted the introduction of the index finger, which could easily estimate the relations of the parts. The finger appeared first to pass through a circular aperture in the resisting wall of the rectum, then into a short oblique canal of less resistance, and probably not half an inch in length, and then through a second circular constriction which was apparently situate in the bladder wall, and then it came in contact with the stone. It had been determined to secure efficient drainage from the bladder by removing the stone through a median perineal opening, which was easily accomplished, removing an oval calculus weighing nine drachms. The fistulous opening was now once more thoroughly exposed; its margins were denuded of mucous membrane; and its sides were approximated by the introduction of ten catgut sutures; the incision made in the posterior wall of the gut was closed by a line of suture through the lining membrane, a line of buried, and a continuous suture through the skin; large drainage tubes were introduced into the bladder and rectum, and securely fixed in position. In the after-treatment milk was excluded, and he was restricted to the use of Leube's beef solution.

Nov. 24. The tube was removed from the rectum, the wound in the posterior wall of which was not entirely healed.

27th. Tube was removed from perineal incision. There was no escape of urine from the rectum after the operation, and examinations made November 25, and Dec. 3 and 11, found the fistulous communication completely closed, and the patient was dismissed cured.

DR. ALFRED C. POST referred to a case, occurring a number of years ago, in which the patient attempted to jump over a broomstick, and the end of the stick penetrating the rectum and passed through into the bladder; he had symptoms of peritonitis, it was said, at the time of the accident. In the following year, when the patient was brought to him, he was suffering from difficulty and pain in passing his urine. On sounding him Dr. Post found a vesical calculus. When the injury was received a circular piece of the seat of the pantaloons was found to be absent. Having ascertained the existence of the calculus, he treated the case by lithotripsy, and on three or four occasions the stone was crushed and fragments passed; it was before the time of Bigelow's apparatus; and at the last crushing, while attempting to withdraw the instrument, he found that an object of considerable size was held in the grasp of the lithotrite, and was removed with some difficulty. On examination, it was found to be the piece of pantaloons which was carried into the bladder at the time of the accident, where it had become the nucleus of the calculus; there was no fistulous opening. The patient recovered perfectly.

DR. GEORGE A. PETERS said that some years ago Dr. Weir had a case somewhat similar to that mentioned by Dr. Post. It was one in which the bladder had been penetrated by a bullet. Dr. Weir crushed the stone, and had the same experience while crushing. He withdrew the body with the lithotrite, and it proved to be a piece of the soldier's pantaloons, which had become the nucleus of the stone.

DR. L. A. STIMSON said that in Dr. Briddon's case the exposure of the fistula through the divided anus was extremely satisfactory; it was almost outside of the body, and its surfaces could be very accurately freshened and approximated.

DR. T. M. MARKOE, speaking of cases in which nuclei of calculi had been forced into the bladder, mentioned a case which he saw in consultation with Dr. Livingston, whom he assisted in the median operation of lithotomy. The history was that at the battle of the Wilderness the patient received a gunshot wound in the right groin involving the bladder, from which he had recovered with a urinary fistula. The fistula gave him comparatively little trouble; but symptoms of stone in the bladder gradually supervened, and several years afterward Dr. Livingston performed the operation mentioned. On removing the calculus and dividing it, the nucleus was found to be a piece of the pubic bone which had been driven into the bladder. Another little piece of bone lying by the side of the large calculus was partially encrusted, but had not formed a stone. They then examined the line of the pubis, and found the depression made by the passage of the ball.

There is another case on record in *The Medical and Surgical History of the War*, that of a patient who was shot through the bladder; symptoms of stone developed, calculus formed, and the nucleus of the calculus was found to consist of a tuft of curled hair, which had been carried in from the pubis.

DR. GEORGE A. PETERS referred to a case in which a hairpin was the nucleus of the calculus, and Dr. Briddon had seen a similar case.

DR. L. A. STIMSON referred to a case in which a piece of the stick used in eating snuff was the nucleus of an oval calculus.

These cases were mentioned to show that the shape of the calculus is not always determined by that of the nucleus.

THE PRESIDENT said the method of exposure of the fistula in Dr. Briddon's case must have been very satisfactory. He imagined that we should see a less number of these cases of urethro-recto-vesical fistulæ now that there are so many calculi crushed. He had met with two cases in which a fistula remained after extracting a large stone. In one case he attempted to drain the bladder over the pubis, after the operation on the fistula, the patient being very young—only four years of age. The drainage went on very well, indeed.

DR. BRIDDON said he had seen two cases of recto-urethral fistula following lithotomy—or, rather, one was ano-urethral, because the opening was close to the verge of the anus. One of them, however, was a real recto-urethral fistula, produced not by the wound, but by the expulsive effort to empty a colon largely distended with casein, the patient having been fed on milk. In the case just reported, Dr. Briddon insisted that the patient should subsist exclusively on Leube's beef solution.

DR. CHARLES MCBURNEY then read a paper entitled

TWO CASES OF OPERATION FOR PYLORIC STENOSIS.

(See page 58.)

DR. BRIDDON remarked that the fact that the secretion of urine was diminished in these cases was interesting. We should naturally suppose that it would be, because the secretion of urine is largely due to absorption from the intestinal walls. In his opinion, the danger would be from septicæmia, because of the inability of the kidneys to secrete urine properly. He thought that the very fact that Dr. McBurney was obliged to use an instrument with which to dilate the stenosed pylorus was evidence that his cases were much further advanced than those reported by Loreta, and of necessity the patients would be in a much worse condition for an operation.

DR. MARKOE said it seemed to him that in estimating the propriety of this operation, one point should be taken into consideration, which had been only slightly touched upon in the paper, namely, that the patient, with proper care, can sometimes be kept alive indefinitely. This certainly is the fact in a number of cases of dilatation of the stomach from stenosis of the pylorus. He has now under his care a gentleman who for fifteen years has used the method of washing out the stomach once or twice a day, and is still in very comfortable health. He has also another patient, who, for about nine years has done the same thing, and has maintained a fair condition of health.

Of course, this method of treatment can be carried out only by systematic attention to the patient, but that it can be done should be taken into consideration in estimating the propriety of this certainly dangerous operation in any given case.

THE PRESIDENT said that Dr. Markoe's remarks concerning supporting the patient were entirely endorsed by his own experience. He had two patients who had adopted the treatment of washing out the stomach, and they did it by means of a flexible tube and a simple funnel. In the case reported he thought that life could have been prolonged for an indefinite length of time, but it was a question of remaining in the hospital forever, or of having something done with a view to radical relief.

DR. MARKOE said that in certain cases he could conceive that the operation was justifiable and might be successful.

DR. F. LANGE presented specimens as follows:

INTESTINAL OBSTRUCTION; ENTEROTOMY; IMPACTED GALLSTONE EXTRACTED; DEATH.

On the 19th of September I saw, in consultation with Dr. Roth, of this city, a Mrs. S., about sixty years of age, who for four days had presented symptoms of intestinal obstruction. Dr. Roth had treated her one year before for protracted abdominal colic, due, as he supposed, to impacted gallstone. From that time on she had often presented dyspeptic symptoms, and an inclination to constipation. Her present trouble had commenced, as I am told, by severe abdominal pain. At first cathartics had been given; on the second day, when vomiting set in, narcotics were administered, and when the appearance of stercoraceous matter in the vomit gave the certainty that a severe obstruction of

the gut must exist, washing the stomach had been resorted to repeatedly, with but transient relief.

When I saw the patient on the evening of the 19th of September, peritonitis already existed. The heart action was commencing to get weak; pulse between 120 and 130; no excessive tympanites, and a moderate ascites could be made out. Though the patient's general condition was not regarded as encouraging for an operation, the latter, as the only imaginable means of saving life, was proposed and consented to. It was done about midnight, from the 19th to 20th of September. The cause of obstruction had to be left in suspense. I was inclined to believe it to be some peritonitic pseudo-ligament.

The patient, after a hypodermic injection of brandy, was given chloroform, and laparotomy by median incision was performed. A considerable quantity of turbid, flocculent serum escaped, and after the omental covering had been lifted, the small intestine presented itself moderately distended, and matted together by peritonitic adhesions of more recent date. It was only after a few seconds of tracing the most distended part of the gut that I palpated a hard lump within it, beyond which the intestines were entirely collapsed. It was obvious that the obstruction was caused by this foreign body, which, after longitudinal incision, escaped easily. The wound in the gut was closed by a double row of Lembert's sutures, and the abdomen closed as quick as possible. The patient had got over the operation comparatively well, the latter having lasted only about three-quarters of an hour. Very soon, however, her pulse became almost imperceptible, and in spite of active stimulation, she died after a few minutes of unconsciousness, and about eight hours after the operation. No autopsy allowed.

The specimen, which you see here sawn across, and of which some of the brittle peripheral layers have been broken, has in its centre a crystalline, round nucleus of cholesterin, about the size of a small walnut, around which, in concentric layers, there is a brownish crust, varying in thickness from one-fourth to one-half centimetre, so about two and a half to three centimetres is the average diameter of the concretion. As you see, in the attempt of sawing across a good deal of the external shell has been broken off. The latter is apparently due to apposition during the sojourn of the gall-stone in the gut.

CORRESPONDENCE.

LOCAL ANÆSTHESIA BY COCAINE.

In THE MEDICAL NEWS of January 2, 1886, Professor Dujardin-Beaumetz speaks of having done the operation for phimosis under cocaine. October 24, 1885, a patient, aged thirty-two, presented himself at my office with congenital phimosis. I applied ten minims of a four per cent. solution of cocaine by a dropper between the prepuce and glans penis. After five minutes I dilated with an Ellinger dilator to the full extent of the instrument. This was painless, but not satisfactory as to extent of aperture. I accordingly made a free incision, and introduced the necessary number of stitches, my friend Dr. Wm. L. Taylor kindly assisting me. At the expiration of a week, finding the incision somewhat contracted, I threw into the prepuce about ten minims of a four per cent. solution of cocaine, and completed the operation thoroughly. Both operations were entirely painless, and, although done in the sitting posture, none of the syncopal symptoms mentioned by Dujardin-Beaumetz, were experienced by the patient.

In neither did I wait longer than five minutes after the application of cocaine before beginning the dilatation or making the incision.

At the present writing, January 4, 1886, the results are satisfactory in every respect.

Yours respectfully,

ANDREW GRAYDON.

1437 N. TWELFTH ST., PHILADELPHIA

ABSORBENT COTTON AS AN ELECTRODE COVERING.

To the Editor of THE MEDICAL NEWS.

SIR: In an article on "Absorbent Cotton as an Electrode Covering," which appeared in a recent number of THE NEWS, Dr. Massey, in his statement that "The resistance offered by pairs of sponge-covered and cotton-covered electrodes may be readily compared," etc., appears to have confounded *specific* resistance (*i. e.*, resistance of sponge or cotton) with *contact* resistance. The experiments of Edison, HerbertTomlinson, Barrett, Heaviside, Bidwell, Naccari, Pagliani, and others, have shown that substances do not materially change their *specific* resistance under pressure. Silvanus P. Thompson found in his experiments with coke-carbon, "subjected to pressure varying from less than one dyne per square centimetre up to twenty-three million times that amount, the resistance did not increase by so much as one per cent. of the whole." On the other hand, according to Sir Wm. Thomson, the resistance of *contact* between two pieces of copper (a good conductor) "may be made to vary in a perfectly continuous manner by changes of pressure, from a small fraction of one ohm, up to a resistance of many thousand ohms," and this is practically what Dr. Massey did with his electrodes. It is not clear in his results that the *specific* resistance of sponge when conjoined with the high resistances of the human body, proves it to be a less or more suitable covering for electrodes than chamois skin, patent lint, cotton cloth, etc.

I do not know what battery cell Dr. Massey used, but taking his own figures, and estimating with the aid of the data furnished in the report of the Battery Committee of the Franklin Institute Electrical Exhibition (see *Franklin Institute Journal*, April, 1885), using the Leclanché disque, one of the cells having the lowest internal resistance, 1 ohm, and Flemming's Leclanché portable, having the highest, 13.5 ohms. Under the most favorable circumstances (*i. e.*, cotton, heavily pressed together) the external resistance of the circuit was 375 to 625 ohms. Allowing 100 ohms for the metal circuit, there are left 275 to 525 ohms as the *resistance of the cotton covering*.

Now, Dr. Massey advises "*two or three layers*,"[1] and confidently asserts "*it need not be feared that additional layers will add much to the resistance of the circuit*, as the experiments described below show that wet cotton, deprived of its natural oil, is a much better conductor of electricity than wet sponge." As it is apparent

[1] Italics are mine.

that each layer of cotton will add 275 to 525 ohms resistance, according as the battery cell used is of low or high internal resistance, I think there is good reason to question the value of his results.

If uniformity of resistance is aimed at in selecting an electrode covering, it will be found, not in absorbent cotton of *variable* thickness, but in some covering of *uniform* thickness, as cotton-cloth, patent lint, or chamois skin, long since recommended by Erb and De Watteville.

Respectfully,

Granville Faught.

115 N. Fifteenth Street, Phila.,
January 6, 1886.

NEWS ITEMS.

NEW YORK.

(*From our Special Correspondent.*)

The County Medical Society is very much interested in a suit brought against Dr. A. S. M. Purdy, a well-known practitioner, by a patient, who claims that through his action she was removed from her home, shut up in the Smallpox Hospital upon Blackwell's Island, when she did not have that disease, and was discharged by the hospital physician. The facts are, that Dr. Purdy, after calling in counsel, decided the disease to be smallpox. He reported the case, as he was bound, to the Health Department, and one of its inspectors, Dr. C. E. Lockwood, saw the woman and recommended her removal. A verdict for several hundred dollars was obtained by the plaintiff, the judge, in his charge, evidently siding with her, and holding that Dr. Purdy had "set the machinery in motion which led to her removal." No one at all familiar with the law can doubt for a moment that the Health Department is alone responsible, and that Dr. Purdy simply did his duty, and if he had not done as he did would have been subjected to a heavy fine. Several thousand dollars have been contributed for the purpose of appealing the case.

Health Officer of the Port.—A lively fight is being made for the position of Health Officer of the Port. Among the names prominently mentioned are those of Austin Flint, Jr., F. R. S. Drake, Hutchinson, and Lewis Foster, the last of whom is regarded as the "dark horse." The present incumbent has a staunch supporter in Senator Platt.

Am Ende, the Hoboken druggist, has just been acquitted. It will be remembered that through his carelessness morphine was substituted for quinine, and two young women were poisoned. One of them was the fiancée of a young Dr. Lowenthal, who nursed her through her last illness. The claim of temporary insanity was urged by the defendant. However flimsy such a plea may ordinarily be from a medico-legal standpoint, much sympathy is felt for the defendant. It is well known that at the time of the accident he was in a most deplorable state of mind. Many druggists are cognizant of his peculiarities of mind, his forgetfulness and absent mindedness. Am Ende is known as the inventor of absorbent cotton, and has had more to do with the success of antiseptic surgery than any person in the country, except the surgeons themselves.

Unlicensed Practitioners.—The pathway of the counsel to the County Medical Society is not one of roses. He has arrested all manner of irregular practitioners, the last of whom has sued him for false imprisonment. A general crusade against counter prescribing is about to be inaugurated.

The demand for cocaine has, like that for bromides and chloral, extended to the general public. One druggist sells no less than six ounces each month.

CINCINNATI.

(*From our Special Correspondent.*)

St. Mary's Hospital.—The following nominations, made at a recent meeting of the staff, have been confirmed by the authorities of this institution:

Dr. Adolph Grimm, to fill a vacancy in the medical staff occasioned by the resignation of Dr. Herman Wilfert, whose ill-health has compelled him to seek a more healthful climate.

Dr. E. W. Walker, promoted to the surgical staff.

Dr. James M. French, appointed Pathologist and Microscopist.

Within the last year, Dr. Frederick Kebler was also appointed to the medical staff.

St. Mary's Hospital ranks, in size, as the second in the city, having a capacity of 300 beds. It is under the management of the Sisters of the Poor of St. Francis, and was the first hospital opened in this country by that order. Although open to patients of every nationality and religion, it is patronized chiefly by the German poor.

Academy of Medicine Reports.—At a recent meeting of the Academy of Medicine, the custom of certain journals publishing unauthorized and very incorrect reports of the Society was severely criticised, and steps were taken to prevent such occurrences in the future. The accurate reports of The Medical News, however, received the approval of the Academy.

MONTREAL.

(*From our Special Correspondent.*)

Mortality Statistics for 1884–85.—The total number of deaths from all causes in 1884 was 4358, in 1885, 7885; increase of deaths in '85 over '84, 3527. This enormous increase is, of course, principally due to the smallpox epidemic which has been raging here for the last six months, but, exclusive of the deaths from smallpox, there was last year an increased death-rate of 363. This increase was due chiefly to an epidemic of measles and diphtheria, which occurred last spring. In 1884 there was not a single death from smallpox, but in 1885, in the city proper, the deaths from this disease reached the large number of 3164. If the deaths from smallpox in the suburbs be added, the total would amount to nearly 4500. The suburbs of Montreal, though continuous with the city, are not within its boundaries, but practically belong to it for statistical purposes: that is, if the statistics are to be worth anything.

Of the 3164 deaths from smallpox occurring in the city proper, 3067 were Roman Catholics and 97 were Protestants. The Protestant population comprises about one-third of the whole, and is well vaccinated; the Roman Catholics, with the exception of the Irish, among whom the mortality has been very small, are nearly all

unvaccinated. Here, then, is another nut for the anti-vaccinationist to crack.

The total number of burials in the Roman Catholic cemetery (which buries people both from the city and surrounding municipalities) last year (1885) was over ten thousand, the year before (1884) only five thousand.

Anti-vaccination Society.—An anti-vaccination society has lately been established here. The president is a notorious quack doctor, who lives by preying on the fears and credulity of those unfortunate youths who are afflicted with sexual hypochondriasis. He has the distinguished honor of holding a Philadelphia degree, supplied, for a small honorarium, by that king of doctor-makers—Buchanan. The vice-president is Dr. Coderre, and the members consist of all the peculiars and anti's in the neighborhood who are in fear of being fined by the health court.

The College of Physicians of Philadelphia held its annual meeting on January 6th, and elected the following officers and standing committees for the year:

President.—Dr. S. Weir Mitchell.

Vice-President.—Dr. John H. Packard.

Secretary.—Dr. Isaac Norris.

Treasurer.—Dr. Charles Stewart Wurts.

Honorary Librarian.—Dr. James H. Hutchinson.

Recorder.—Dr. J. Ewing Mears.

Censors.—Drs. Lewis Rodman, William Goodell, Alfred Stillé, Samuel Lewis.

Councillors (to serve until January, 1889).—Drs. Richard A. Cleemann, William Thomson.

Committee on Publication.—Drs. James H. Hutchinson, Robert P. Harris, Arthur V. Meigs, J. Ewing Mears.

Committee on Library.—Drs. I. Minis Hays, Samuel W. Gross, Morris Longstreth, George C. Harlan, William Osler.

Committee on Mütter Museum.—Drs. William Hunt, John H. Brinton, Morris Longstreth.

Committee on Hall.—Drs. Horace Y. Evans, Thomas Hewson Bache, J. Ewing Mears, Morris J. Lewis, William Barton Hopkins.

Committee on Lectures.—Drs. Joseph Leidy, William Goodell, William F. Norris, John H. Packard, Samuel W. Gross.

Committee on Directory for Nurses.—Drs. William W. Keen, Wharton Sinkler, James C. Wilson.

The Annual Meeting of the Philadelphia County Medical Society was held on Wednesday, January 6, at 4 P. M., the President, R. J. Levis, M.D., in the Chair. Over two hundred members were present, constituting the largest meeting of the Society ever held.

It was moved that the order of the day be suspended, and that, in accordance with the custom of the Society, the polls be opened forthwith and kept open until six o'clock. Numerous technical objections and dilatory motions were interposed, but finally, when a vote was reached, the motion was carried by an overwhelming majority.

Dr. D. Hayes Agnew, in a brief speech, moved that the list of delegates to the American Medical Association and to the Pennsylvania State Medical Society, which he then presented, be substituted for the list presented last October by the Committee on Nominations. Numerous objections and dilatory motions were again interposed; but finally, after considerable delay, the previous question was called and the yeas and nays demanded, Dr. Agnew's motion was passed, and the list of delegates he presented were elected by ballot, receiving 169 votes to 36 for the opposing candidates.

Dr. Agnew then offered the following resolutions, which were adopted with but a single dissenting vote:

Resolved, That at its annual election of delegates to the American Medical Association and to the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society desires to express its regret at the action of the American Medical Association at New Orleans, in view of the injurious results which have followed to professional harmony and to the prospects of the International Congress.

Resolved, That the delegates from this Society be instructed to endeavor to procure such modification of that action as may best conduce to the reëstablishment of professional harmony and to the success of the Congress.

The following officers were then elected for the ensuing year:

President.—Dr. R. J. Levis.

Vice-Presidents.—Drs. Wm. R. Cruice, Chas. Wittig.

Recording Secretary.—Dr. S. Solis-Cohen.

Assistant Secretary.—Dr. Benj. F. Nichols.

Corresponding Secretary.—Dr. M. S. French.

Reporting Secretary.—Dr. Wm. H. Morrison.

Treasurer.—Dr. L. K. Baldwin.

Censor.—Dr. F. P. Henry.

Librarian.—Dr. C. M. Seltzer.

New York Academy of Medicine.—At the annual meeting of the Academy, held on January 7th, the following were elected officers for the ensuing year:

Vice-President.—Dr. H. D. Noyes.

Corresponding Secretary.—Dr. Wesley M. Carpenter.

Treasurer.—Dr. W. F. Cushman.

Trustee.—Dr. G. A. Peters.

Committee on Admissions.—Dr. J. H. Emerson.

Recording Secretary.—Dr. A. M. Jacobus.

Committee on Library.—Dr. W. H. Katzenbach, full term; Dr. Laurence Johnson, short term.

Delegates to State Medical Society.—Drs. W. R. Birdsall, R. W. Amidon, W. E. Bullard, G. Bacon, and A. S. Hunter.

International Medical Congress.—Dr. R. J. Levis, of Philadelphia, having been notified recently that he was appointed a Vice-President of the Section of Surgery, has declined the position because of his conviction of the impossibility of organizing a successful Congress under the existing circumstances.

A New Medical Journal.—The first number of the *New Yorker medizinische Presse*, a monthly journal designed as a medium for the use of German American physicians, has just been issued. It is an octavo of 48 pages, containing original articles, editorials, and reviews, and gives promise of forming a valuable addition to journalistic literature.

Sanitary Inspection.—The inspectors in Chicago during the first nine months of the year, made 63,264

examinations, of which 51,381 were made in places of habitation, 10,499 in factories, stores, and other places of employment, and 1384 were made according to law in new buildings in process of construction.—*St. Louis Courier of Medicine*, December, 1885.

Yellow Fever Inoculations in Brazil.—Advices from South America state that Dr. Freire, of Rio de Janeiro, has already inoculated 5000 persons in Brazil for the prevention of yellow fever, and that not one of this number has died of the disease, although the great bulk reside in centres of infection.—*Lancet*, December 19, 1885.

Cremation in Germany.—A member of the German Reichstag is stated to have tabled a petition in favor of the introduction of optional cremation. The petition bears more than 23,000 signatures, tendered in various towns and cities of the empire, among them being those of 1942 physicians, 1006 lawyers, 849 professors and teachers, 361 women, and 13 clergymen.

Open Prizes of the Madrid Academy.—The Medico-Chirurgical Academy of Spain commenced its sessions for the year on November 30th, when a paper was read by Señor Ustariz on "The Necessary Reforms in Hospitals for the Practice of Antiseptic Surgery." The subjects for the academical prizes for the next year were announced, viz.: 1. Academy Prize: What Modifications has the Panspermist Doctrine introduced in the Treatment of Internal Diseases considered or suspected to be of Parasitic Origin? 2. Señor Morales' Prize: Progress in Operations on Bones; Criticism. The first prize is 250 pesetas ($50); the second, 750 pesetas ($150). The essays may be written in Spanish, Portuguese, French, Italian, English, or German, and are to be sent in to the President, directed "Montera, 22 Bajo, Madrid," before September 15, 1886.

Mr. Erichsen, of London, has been defeated in his candidacy for Parliament as the representative of the University of Edinburgh.

Dr. Heywood Smith.—The conduct of Dr. Heywood Smith in reference to the girl Eliza Armstrong has been investigated by the Royal College of Physicians, who have received from him, and carefully considered, his explanations and apology; and at a general meeting of the College, held on Friday, December 18th, specially summoned to receive the report of the President and Censors on the subject, the following resolution was adopted: "The College having considered the statements made by Dr. Heywood Smith, and his apology through the Censors' Board, while acquitting him of deliberate intent to do evil, desires to put on record an opinion that he has committed a grievous error in connection with the Armstrong abduction case, which has brought discredit on himself and the profession to which he belongs. The College, therefore, regards his conduct as deserving the severest censure, and requests the President to express the views of the College, and to reprimand him accordingly." The President has accordingly addressed to Dr. Heywood Smith a severe reprimand, and warned him to be careful as to his conduct in the future.

M. Mathias Duval has been named for the Chair of Biology in the Paris Faculty, as the successor of the late M. Robin.

Official Recognition of Female Physicians.—The first official recognition of female medical practitioners has just been made by the Italian government. The recipient of this distinction is Signorina Terne, M.D., whom Queen Marguerita has appointed one of her physicians in ordinary.

Heidelberg University.—The 500th anniversary of the foundation of the Heidelberg University will be celebrated next August. The celebration will be held in a hall specially constructed for the occasion, capable of holding 5000 persons.

The Russian medical authorities have sent Dr. Raplshevski to Spain to study the epidemic of cholera, and to report on the results of inoculation.

NOTES AND QUERIES.

AN UNUSUALLY LONG UMBILICAL CORD.

To the Editor of The Medical News.

Sir: I saw, in The Medical News of November 14, 1885, a note from A. H. Garrett, M.D., of Oswego, Kansas, under date of November 2, 1885, stating the length of an unusually long umbilical cord, and like him, thinking it might be of some interest in statistics on the subject, I will state the length of one I found in my practice recently.

On December 30, 1885, I delivered a white woman of a female child whose umbilical cord measured four feet and one-fourth inch. The cord encircled the neck three times and the body once. The mother, a multipara, stated that the labor was two weeks before term. Child weighed nine pounds. It and mother were in healthy condition and labor normal.

Respectfully,
J. C. Cowan, M.D.

Mass Point, Mississippi,
January 6, 1886.

A VESICAL CALCULUS OF UNUSUAL SIZE.

To the Editor of The Medical News.

Sir: The weight of the vesical calculus removed by me from a lad fourteen years old, and exhibited at a meeting of the New York County Medical Association December 21, 1885, is *seven ounces and four scruples*, Troy weight, and not four ounces and four scruples, as reported.

The patient in now convalescent, and will be discharged from the hospital in a few days. Please give this correction a place in your valuable journal, and oblige

Yours truly,
Theodore R. Varick, M.D.

Jersey City, January 9, 1885.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT OF THE U. S. ARMY, FROM JANUARY 5 TO JANUARY 11, 1886.

McParlin, Thomas A., *Colonel and Surgeon.*—Now awaiting orders in New York City, ordered for assignment to duty as Medical Director, Department of the Platte, on January 24, 1886.—*S. O. 5, A. G. O.*, January 7, 1886.

Goddard, Charles E., *Major and Surgeon.*—Died at Fort Yates, Dakota Territory, January 4, 1886.

Munn, Curtis E., *Captain and Assistant Surgeon.*—Ordered from Department of the East to Department of Columbia.—*S. O. 4, A. G. O.*, January 6, 1886.

Shannon, William C., *Captain and Assistant Surgeon.*—Ordered from the Department of the Platte to the Department of the East.—*S. O. 4, A. G. O.*, January 6, 1886.

McCaw, W. D., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Lyon, Colorado, and ordered for duty at Fort Leavenworth, Kansas.—*S. O. 1, Department of Missouri*, January 4, 1886.

Swift, Ebenezer, *Lieutenant-Colonel* United States Army (retired).—Died near Hamilton, Bermuda, December 24, 1885.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLVIII. SATURDAY, JANUARY 23, 1886. No. 4.

ORIGINAL LECTURES.

PROLAPSE OF THE VAGINAL WALLS, DUE TO LACERATION OF THE CERVIX AND INJURY TO THE VAGINAL OUTLET.

A Clinical Lecture delivered at the Jefferson Medical College Hospital, January 12, 1886.

BY THOMAS ADDIS EMMET, M.D., LL.D.,
SURGEON TO THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK.

PROFESSOR THEOPHILUS PARVIN introduced the lecturer with the following words:

GENTLEMEN, the names of the two Americans who are most identified with the advance of knowledge in the diseases of women, are names of gentlemen who have graduated at the Jefferson Medical College. Further, not only in this country are these names most identified with this branch of medicine, but throughout the whole world they stand preëminent among those who have advanced our knowledge of the diseases of women.

One of these gentlemen, Dr. Marion Sims, passed away two years ago; the other is with us to-day to teach you and to teach me; and if there be a man in all the profession whom I especially call master, it is he whose lessons I have tried to teach, and whose lessons I shall continue to teach. To-day you have the opportunity of seeing and hearing the master himself, Dr. Thomas Addis Emmet.

DR. EMMET said:

GENTLEMEN, I am sure that I cannot find words to reply,—to say what I would like to. I feel it a great compliment to be here to-day, which is something that I could never have dreamt of in my student days. But I am almost like Rip Van Winkle, for it is thirty-six years since I left this college, and I am sorry to say that this is the first time that I have been in it since I was graduated. The professors, and I believe all that were then connected with the school, are dead. I greatly appreciate the compliment of being asked to speak to you, but as we have a great deal to do, I shall not waste any more time but proceed to business.

CASE I.—I have just examined the case which is being put under ether. It is a case of procidentia, occurring in an elderly woman, that is prolapse, entire, of both the vagina and uterus. There are several causes for this condition, but it is generally due to a laceration of the cervix. I believe that, as a rule, procidentia occurring in women who have borne children, is due to injury of the cervix. We have, however, exceptions to the rule in women who have not borne children. The condition may be then brought about by lifting and straining where there is a small fibroid favorably situated, or with the bladder distended.

Various methods for holding up the uterus have been employed. If a proper pessary could be devised, it would not be necessary to resort to any surgical measures; but unfortunately mechanical means do not answer. The object of any procedure to cure procidentia, is to place the uterus in such a position that the circulation can be reëstablished, so that the involution, which has been arrested, may go on. You may have a case of marked procidentia in a woman whose last child was born twenty years previous, in whom there is apparently no laceration, yet the line will be there, and if the dense tissue is removed from the cervix and the parts brought together, in about forty days, as the Bible points out, it will be found that the uterus has returned to its natural size. Since we have recognized the fact that procidentia is due to laceration of the cervix, we operate for that lesion, and have to resort to the operation for supporting the uterus by an operation on the vaginal wall in comparatively few instances, but when it becomes necessary to do it, as it is in this case, we perform it according to the method which I shall explain.

The first operation to remedy this difficulty was suggested by Marshall Hall many years ago, although I believe that neither he nor any one else, before Sims, attempted to put it into practice. Marshall Hall suggested that two parallel surfaces be denuded on the anterior wall of the vagina, and that these denuded surfaces should be brought together with sutures. In that way a double vagina would be formed. The operation proved an entire failure, for one fold after another of the anterior wall of the vagina would come down against the line of union until, if absorption did not take place and the whole line give way, the septum would be gradually dilated until it came against the posterior wall of the vagina, and the operation would thus prove a failure, and this was a question of only a few weeks.

This operation was modified by the late Dr. Sims about the year 1846. He brought these surfaces together at one end near the neck of the bladder, and passed the sutures in the same way across the undenuded portion. This was a great advance, but before going further, I should mention that Dr. Sims's first attempt was not as I have described. He was like the man who was "death on fits;" if he could get his patient to have fits, he knew where he stood. This was about the time that Dr. Sims was introducing his operation for vesico-vaginal fistula. He attempted to cure the trouble by removing the excess of vaginal tissue, and making a vesico-vaginal fistula, and then bringing the surfaces together. But he failed to enter the bladder, as he did not realize that the bladder and vagina are in contact to a very limited extent, and confined to the triangular space between the mouth of the ureters and the urethra, each side of which does not measure more than one inch. This operation, without entering the bladder, was wrong in principle, and it failed. When this tissue was crowded up against the bladder it encroached greatly upon the cavity, and pressed more or less upon the ureters, setting up irritation and cystitis, and leading to dilatation of the ureter and renal disease. I have followed up

several cases where that operation was done, and the result was as I have described; I am, therefore, sorry to see that within recent times this form of operation has again been proposed.

Having failed with this, then Dr. Sims took the Marshall Hall operation, and modified it by bringing the lower extremities of the parallel surfaces together, making the denuded surface of a V-shape. This, as I have said, was a great advance. If these surfaces were brought together in the median line, it acted as a crutch in front of the uterus to keep it up. The fold thus formed grasped the enlarged cervix and supported it, provided the tissues below met in the median line. But after the lapse of a few months, when involution had taken place, this fold no longer grasped the uterus, and it would sometimes get behind the pouch and come down as before.

Having seen these cases, where there was a great deal of trouble, I modified the operation. This consisted in making a cross-section in front of the cervix, thus uniting the extremities of the V-shaped denudation. I had no fear in shutting up the cavity, although Sims always left an opening in order that fluids might escape, and yet nothing but a little mucus could be secreted, and this would be easily absorbed. The principle is this, if you can support the uterus and allow involution to take place, the over-stretched tissue will retract, and the vagina will return to its natural size. Although there is a cavity left between the surfaces at the time of the operation, there will be no cavity when the tissues have retracted. It is like a piece of over-stretched India-rubber—if the traction is taken off, there will be retraction. The closure of this cavity formed no objection to the operation, while the opening left by Sims was rather a weak point. I thought that I had reached perfection in the operation, for when properly performed, it was all that could be asked; but I found that the method could never come into general use, because it required constant practice to bring the line of union always in the median line. If the upper stitches were not properly introduced, denuded and undenuded portions would be brought together, and the operation would fail. It required an expert to bring the parts up in such a way that they would fold on themselves instead of coming together as with a running-string. I then made the modification of the operation which I shall use to-day.

In these cases, the uterus is retroverted, and the first thing to be done is to antevert it, and then pass a probang into the cul-de-sac of the vagina, and thus keep the uterus thrown forward. Now place the patient on the left side and introduce Sims's speculum. Then find three points, one on each side of the uterus and a third in front, which can be brought together without undue traction. A surface is then denuded at these three points, and the two lateral ones are brought in apposition with the median point, and secured by an interrupted silver suture. When this suture has been twisted, a fold is brought up in front of the cervix, by which the uterus is held up. We have then two long folds formed by the excess of tissue and extending toward the vaginal outlet, and which have to be disposed of. One advantage of this method is that it dispenses with the hand of an assistant, for the uterus cannot now come down. The old operation was a bloody one, for the whole surface had to be denuded before the sutures could be introduced. In the present operation, having inserted the first suture, a portion of the crest of the fold can be denuded on each side for half an inch in extent, and readily brought together, as several sutures are introduced. Having done this, the process is continued until all of the folds have been turned in.

When there is an excess of loose tissue about the urethra, it is necessary to dispose of the mass in a special manner, as it cannot be gotten rid of by continuing the line from the cervix. If we separate in the median line, at the crest of the cystocele, and go off to each side so that the line of union on the anterior wall is A-shape inverted, this excess of tissue can all be drawn up. But there is almost always a break in the line of union at the junction of the three lines, so that a second operation becomes necessary. To overcome this difficulty, it is better to stop turning in the tissues along the median line just at the crest of the cystocele. Then denude below two lines near the neck of the bladder, and across the vagina from one sulcus to the other, so that these surfaces represent a crescent in shape, with undenuded tissue in the centre. If these freshened surfaces have been made at the proper distance from each other, all the loose tissue about the urethra will disappear as soon as the sutures have been secured.

You must bear in mind, as I have already stated, that the whole object to be gained by any operative procedure in procidentia is to hold the uterus at such a position in the pelvis that the circulation can be restored, thus giving a chance for the involution which has been arrested to be completed. We cannot gain this object by any form of pessary yet devised, for the downward pressure will force the folds of tissue into every crevice, causing sloughing, or with the effect of dilating the vagina still more.

The success of this operation depends upon the use of just the proper amount of traction in bringing the parts together. The denuded surfaces should not be separated any more than is necessary to bring the parts in apposition. If the denudation extends any further than this, it makes no difference what kind of sutures you use, they will cut out. No suture can stand the persistent traction of the pelvic fascia. It is an art to know how far apart you should denude these surfaces.

(The patient was now brought in and operated on in the manner described.)

The operation is now completed by turning in the excess of tissue, and the anterior wall of the vagina is of the size that it was before the birth of this woman's first child. The term "narrowing the vagina" is a misnomer. You cannot narrow the vagina, and the term should never be used. This operation is not, therefore, for narrowing the vagina. The sulcus on each side of the vagina is in direct connection with the fascia and connective tissue of the pelvis. If you bring traction on these, no suture could stand the strain. You are to turn in the tissue as this woman would do by a plait in her dress if it was too large for her. You therefore do not narrow the vagina. You cannot approach the surfaces any nearer to each other than they were before the birth of the woman's first child. It is only the excess of overstretched tissue that is removed.

Let me now show you on this towel how to introduce a silver suture. Suppose that we have here a slit which I desire to bring together. Dr. Sims, to whom we are

indebted for the introduction of the silver suture, at first laid down the rule that it was absolutely necessary that the suture should be passed equidistant from the edge of the wound, for if this were not done, the denuded and undenuded tissue would be turned in together, as the sutures were twisted. This difficulty is overcome by shouldering the suture, as it is termed. Take a tenaculum and catch the edge of the wound at the point where you are to introduce your needle; then evert the edge of the wound, and see where you want to bring the needle out. You then advance the needle against the tenaculum as a point of counter-pressure until the point of the needle can be caught with the forceps; then catch the opposite side of the wound, and rotate it outward, and note where you want to introduce the needle. Then bring the needle out anywhere, so that you get it through. The next thing is to make a shoulder or sharp angle on the suture, so that the angle of each will come together at the line of union. Here is the important point where so many fail. Here is an instrument introduced by Dr. Sims, and called a shield. If the wires are passed through the slit, and twisted at a right angle to the direction of the shield, as is usually done, it is only an accident when the suture is not twisted too tight, so as to strangulate the tissues—and with failure as the rule. But if I bend the wires, now in the grasp of the forceps, over the thin edge of the slit, so that the forceps and handle of the shield lie together in the same direction, and twist the sutures until that angle formed by the two wires is no longer seen, the edges of the wound will be only just in contact. If the twisting is carried any further, the parts in the loop of the suture will be strangulated.

Next it is most necessary to make the suture lie flat. To do this lift the suture at the angles with a tenaculum as a fulcrum, and when you have bent the extremity over, make pressure downward with the same tenaculum at the point where you wish to cut the end of the suture off; it will then lie perfectly flat. I recently removed a suture which I had inserted seventeen years ago, and since then the woman has had two or three children. The suture was lying as flat as when it was inserted. It was, however, up to one side of the cervix. It is by attention to these details that success is attained. I would advise you to take a towel and practise what I have told you, until you acquire the knack of properly introducing the suture. When you are able to do this, you have acquired one-half the art of plastic surgery.

CASE II.—Gentlemen, I have here a case of double laceration of the cervix very deep, and also partial procidentia. To-day the laceration will be operated on, but the operation on the vaginal wall for procidentia if needed must be performed later, for the operation would take a long time, and even if I were to do it, you would not be able to see much. I can occupy the time much better by saying what I have to say about laceration of the cervix, and shall therefore ask Dr. A. P. Dudley, who was, a short time since, one of the house surgeons of the Woman's Hospital, to do the operation. He will do it just as I would do it.

There is a great deal to be said on the subject of laceration of the cervix. The lesion is of frequent occurrence. I have no doubt that Eve's cervix was lacerated, and since that time the cervix of nearly every woman who has borne children has been lacerated. I do not believe that a woman can give birth to her first child without more or less laceration of the cervix. It is a very important point to know when an operation is necessary. There are a great many cases of laceration of the cervix in which no interference is required. I sometimes think that almost more harm than good has been done by the operation, although in so many cases there is no operation that can take its place or accomplish so much. It is important to know under what circumstances an operation is required. I have noticed that in the cases in which interference is called for, there has been, as a rule, a bad getting up after the labor. If a woman has no milk, or does not get up well, it is always a suspicious sign of laceration of the cervix, with the occurrence of a certain amount of septic inflammation in the pelvic tissues, and it is probable that the laceration will not heal so long as that inflammation exists. I believe that if obstetricians understood this matter more thoroughly, and gave a little more personal attention to a patient who has been delivered with forceps, or who has had a hard or rapid labor, and determine whether or not pelvic inflammation exists, so that it may then be treated, in the majority of cases nature would readily repair the injury, and that within a few years the operation will be called for less frequently than it is at present. If this pelvic inflammation exists, it should receive proper treatment immediately after labor, for at this time treatment will accomplish more in a few weeks than can be gained in months, if the disease is allowed to go unchecked. The early recognition of the trouble is therefore of great importance, as the reparative process would be as active as that which would take place in the uterus under favorable circumstances.

If we have the case going on beyond that time, with involution arrested, with the uterus enlarged, and more or less pelvic inflammation or thickened broad ligaments, which is the usual lesion, the case must now be properly prepared before the cervix should be operated upon. Until the preparatory treatment has been carried out, it is impossible to say what cases require operation and what cases do not. This is where the mistake is made by many. The patient must be gotten as well as possible before an operation is performed. What you wish to do is to cure the pelvic inflammation and restore the circulation to its proper condition. So long as there is cellulitis, or any form of pelvic inflammation, the circulation must be obstructed, causing the parts to roll out and to exaggerate the existing lesion. I at one time thought that the rolling out was due to mechanical causes such as standing or walking about, but I am now satisfied that it is due to obstruction of the pelvic circulation. I was once astonished to find that a young girl, with whose history I was well acquainted, apparently had a laceration almost to the internal os. She had cellulitis, and I supposed that an abortion had been produced. I treated the cellulitis, and as the inflammation improved, the parts rolled back, and she then had a virgin os. I mention this case to show the importance of proper preparatory treatment.

How are you to treat such a case? If possible, she should be treated in a hospital. She should be taken from her home. She is unfit to be a wife, and must be in a position where she has no care or responsibility, and to vegetate, if possible, for a few months. The mind

has so much influence over the body, especially in this condition, that it is important to keep the mind tranquil. The main treatment is hot water injections, but these must be given properly. They should be given by the hand syringe and not with the siphon syringe. Heat, cold, and electricity will cause the vessels to contract and bring about the condition we desire. Electricity will cause the vessels to contract, but only while the current is passing. Cold will cause the vessels to contract, but unfortunately when reaction occurs, the vessels become larger than before. Heat at first produces a temporary congestion, but if the application is prolonged, contraction of the vessels is produced; therefore, the reaction from heat is contraction. We wish to cause contraction of these vessels and if so we can starve out the cellulitis and bring about absorption of the inflammatory deposits present. I hold that there is something in the jet of the hand syringe. It probably acts on the same principle as the dashing of water into the face of a person who has fainted. If you give a woman a douche with a siphon syringe and prolong it for an hour or two, you get about the same effect as from a fifteen minute injection with a Davidson's syringe. If the siphon syringe is used, it must be prolonged for a considerable time. The use of hot water, with the hand syringe, as the patient lies on her back with the hips elevated, has the effect of puffing out the vagina, so that the hot water comes in direct contact with the vessels, and will accomplish more than any other means of treatment.

The application of iodine will prove of the greatest benefit. This is not to be applied to the uterine canal for fear of increasing the cellulitis. I have not made an application to the uterine canal during the last five or six years, except in cases of vegetations, where I have been obliged to use it to control hemorrhage. There exists the closest relation between the surface of the uterine canal and the peritoneum. If you have an assistant, Sims's speculum may be used, with the patient on the left side so that the iodine may be applied to the posterior cul-de-sac and to as much of the vagina as possible without coming in contact with the external orifice. The preparation which I use is known as Churchill's tincture of iodine, and is four times stronger than the ordinary tincture. If you have no assistant, the woman may be placed in the knee-chest position, so that Sims's speculum can be held in one hand as the application of iodine is made with the other.

If you have the patient in the hospital under control, you can daily put a pledget of cotton, saturated with glycerine, under the well side of the uterus, behind, in front, or in such a way that the uterus shall be raised somewhat so as to take the drag off of the thickened broad ligaments. A pessary is not applicable, for it will press against one broad ligament or the other, or if the inflammation is behind the uterus, you cannot apply it at all. You make the best progress when you have the patient directly under your eye, and can daily use these pledgets of cotton so as to raise up the neck and take the strain from the shortened broad ligaments, for this does much to restore the circulation in the pelvis.

The follicles in the mucous membrane of the cervix, undergo cystic degeneration in this condition and it is very important to get rid of them. As these enlarge and increase in number, they roll out the tissues, to a point where, when cicatrization takes place, the parts are almost strangulated as if a cord were wrapped around the cervix. Everything is to be gained by puncturing these cysts. There are sometimes literally thousands of them, and just as you get rid of them by puncture you help to restore the circulation, and the parts gradually roll back. It is not until the cysts have been emptied, the flaps reduced in size, and the parts have rolled in again that you can tell what cases will require operation. You will be surprised at the amount of improvement which can be brought about in two or three months of this treatment, and its use will lessen the number of operations necessary to be performed on the cervix. If the operation is done too soon, these cysts will be shut up within the flaps as a source of irritation and if you do get the union that is desired, there will be no improvement. On the other hand, even with the uterus four or five inches deep, if the treatment has been properly carried out so that the cysts have been emptied and the cellulitis reduced, it will in the course of three or four weeks after the operation return to nearly its natural size.

I have been speaking of cases of recent origin. You will, however, meet with a class of cases which have extended over a period of years, where the woman has become anæmic and nervous, and presents any number of reflex symptoms, from a pain in the end of the nose to a pain in the toe, for which no reason can be found. She has frequent headache, pain in the back, and particularly in the nape of the neck, which is a common sympton, often sleeplessness, and inability to fix her mind on any subject, or to take any responsibility. In many of these cases, the parts have healed and often there is apparently no laceration, but the whole uterus, and especially the neck, remains too large.

If you take a case of enlargement of the uterus, from any ordinary condition, you will find, as you run your finger into the cul-de-sac of the vagina, upon the sides, that the organ is of uniform thickness, so that the portion of the cervix below the vaginal junction is of the same size as the body above. It is a uniform enlargement. If, on the other hand, you take a laceration, whether a fissure exists or not, there is always a certain amount of rolling out, so that you can feel a mushroom-shaped cervix. After the flaps have separated, nature will sometimes go to work and fill in the space between them with cicatricial tissue, or a new growth of tissue, as it has been claimed, until the fissure is filled up, and there is apparently no laceration, and yet in these cases the injury often has been the greatest. The only exception to this rule of rolling out, or club-shaped cervix, as an indication of the injury, is the circular laceration. If the lacerations take place in different directions, from within outward, so as not to reach the vaginal surface, they will open out the cervix so that the finger can be passed to the internal os. This is not an uncommon form of laceration, and there is here no rolling out as is seen in cases of lateral laceration. In the ordinary form of laceration, many think that if they simply denude on each side and bring the parts together, without removing the dense tissue in the angles, that they have overcome the difficulty, and they are surprised to find that they do not get good results. If I place a spool between my fingers, and then bring them together, I have included

a foreign body which will obstruct the circulation. Instead of the uterus decreasing in size after the operation, if this foreign body be left, it becomes larger, and the woman, instead of being relieved, is made worse.

In these cases, where there is no apparent laceration, and the cervix is enlarged, if you take a pair of scissors and cut through the tissues down to the vaginal junction, you will pass through or come to dense tissue. Cut this tissue out, and you may call it cicatricial tissue, new growth, or whatever you choose. It is a clinical fact that, if you do thoroughly remove this tissue and bring the surfaces together, you will relieve the symptoms. An important gain is that you will also cure the anæmia. Why? You know that the sympathetic presides over the genital organs, and also over nutrition, so that the relation is a very close one; therefore, when a source of irritation has been removed, nutrition will promptly assert itself. This is the only way that we can explain the fact that, after the removal of this tissue, the anæmia will disappear, and the woman will sometimes gain twenty or thirty pounds of flesh in a year, and will, at the same time, get rid of the most anomalous reflex symptoms.

I shall now refer to circular laceration. The first step in the operation necessary for the relief of this injury, is to cut open the cervix on each side with a pair of scissors to the vaginal junction, then denude a surface over each flap, leaving a space between large enough to form the uterine canal when these have been brought together with sutures, as in an ordinary lateral laceration. In these cases you will often find an immense number of cysts about the internal os, where the mucous follicles are large, and they can be brought into view and removed, on widely separating the flaps when the parts have been drawn down to the vaginal outlet. Occasionally we are called on to treat cases of lacerated cervix which have been neglected through a long series of years, until the whole cervix has undergone cystic degeneration. I have been misrepresented as opposing amputation of the cervix in such cases. I have never opposed the operation, but have always resorted to it in a certain set of cases. It is bad surgery to shut up these cysts, and it is as impossible sometimes to bring about a healthy condition, as it is to do so in the tissues of a tonsil which has been inflamed for many years. The shortest way to effect a cure is to get rid of the whole diseased tissue. In these cases, I partially amputate the cervix, removing only the diseased tissue with a pair of scissors, and always cover the stump with vaginal tissue by Sims's method. My objection to amputation does not apply to these cases, but to the condition which is claimed to be an elongated cervix. I deny that the flap of a laceration is elongated, even if it appears to be so. I will show you where the explanation of the condition lies, and also how you can cure these cases without amputation. Sometimes where the vaginal canal is very open, the anterior lip will roll out, and the vaginal tissues will become crowded over it, so that the lip will be apparently much longer than the posterior one, but the amount of uterine structure in one is no more than that in the other lip. The appearance is due simply to the crowding down of the vaginal tissues, as in a prepuce. This is proven by the introduction of a sound into the bladder, when the extremity of the instrument reaches a point on the crown of the cervix, which it could not do if its insertion within the vagina was really where it seemed to be. Both flaps can be brought together accurately, by so denuding the vaginal surface, when forming the angle, that one flap shall be as long as the other, and this can be done without any reference to the angle at the uterine canal. If done properly, the tissues on the anterior lip will roll in, or be stripped back, so that the anterior lip will be no longer than the posterior. In these cases I have opposed amputation because I know that the neck is not elongated. There are cases which are termed congenital elongation of the neck of the womb, but these have nothing to do with the condition which I have been describing.

The patient on whom Dr. Dudley is operating has another lesion, which may be described by saying that the running string has been lost from the vaginal entrance. This is what is usually called a laceration of the perineum. Although we shall not have time to operate, I should like to explain the condition. As a rule, the perineal body is not torn by the child's head. It may be torn by the forceps from above downward. This lesion of the perineum is very different from what it is supposed to be. It is a tear directly across the passage and just within the vagina behind the fourchette. The idea is, that when the child's head is pressed against the muscular barrier, and the outlet of the vagina is not dilated enough for it to pass, the canal must be torn at its insertion, if the force behind is able to overcome the resistance in front. It is like a strong man trying to go through a door which is not large enough to permit him to pass through, and, in his efforts, he may carry the doorframe with him; but the force could not be so applied that he would simply break the sill across. The perineum is generally torn when the sphincter is, and when the tear begins and extends from before backward in the median line. The relaxation and protrusion of the tissues, in this case, are due to the transverse tear I have described, and the cicatricial line can be plainly seen. It has separated the pelvic fascia just where it is reflected from the sulcus on each side over the muscles at the vaginal outlet. In no case do the fibres of the levator ani muscle interlace, and often they do not approach within half an inch of each other. When the transverse tear takes place, and the head continues to advance, the connective tissue between these muscles separates, and the muscles themselves are drawn aside, as a curtain, with often not the slightest injury to the skin in front, or to the mucous coat of the vaginal canal. The transverse perineal muscle, from its insertion in the tuber ischii behind, must naturally tend to draw the muscles apart and roll out the tissues, as the lower lip would fall off from the bone if the attachment in front were cut away. In other words, the real extent of injury is an exaggeration. It is very rare that any portion of the skin, or any tissue outside of the vaginal outlet, is torn in these cases.

What is the effect of this? The woman does not suffer from want of support to the uterus when she has what is called a laceration of the perineum. The perineum has nothing to do with its support. A woman's perineum is certainly lacerated when the sphincter is torn through the median line, and yet I have to see the first woman who has complained of difficulty in walking or standing from this cause. That, of itself, shows that it is not the perineum that supports the uterus.

The purpose of the perineum is to support the curve of the rectum and prevent the rectum from bulging into the vagina. When the muscles are separated in these cases, we must have a rectocele. The sulcus on each side of the vagina is in direct connection with the connective tissue of the pelvis. When the parts are normal the upper portion of the vagina is as fixed as the roof of this room. The fascia and connective tissue on each side bring the posterior wall up against the anterior one. It is like taking a rubber tube and making lateral traction: the sides will come together. I claim that separation takes place, across the vagina, behind the outlet, where the vagina is inserted into the muscles. When this occurs, the fascia on each side is divided. As soon as that is done, there is a slacking of all the connective tissue in the pelvis and the woman suffers not from a want of support to the uterus from loss of the perineum, but from want of proper support to the blood-vessels, which, without the needed support, will enlarge indefinitely. After a long time, when the uterus has become heavy from continued congestion, it comes down to the floor of the pelvis, becomes retroverted, and so on, but this is not the case in the beginning. I cannot explain this slacking up of the pelvic fascia better than by describing something that occurred to me when a boy, in the days of trundle-beds. With the springs of to-day you know nothing about the manner in which the sacking-cloth was stretched on these beds. The bed in which the children slept was pushed under a larger one, and the bedding was supported by a piece of canvas or sacking, which was kept tight by means of ropes secured to pins in the frame of the bed. By long usage, these pegs had become worn at the bottom, and I well recollect the time we had when the rope would slip off from the pins. When several loops of the rope slipped at the foot of the bed, the sacking would of course become slack up the middle. Suppose the rope could not be put on the pins again, with the condition I have drawn here on the board, could we not overcome the difficulty by bringing up the slack in a fold on each side across the lower angles of the bed? This fold is just in the same direction and relatively in the same position where we bring up the tissues in the vagina, with the object of making traction on the fascia and connective tissue of the pelvis, that the proper support may again be given to the rectum and bloodvessels. To do this, and on the same principle as I did in the other operation on the anterior wall, to dispose of the excess of tissue about the urethra, you are to denude a crescent with a horn extending into the sulcus on each side. This denuded surface will, therefore, extend across the vagina, and just within its entrance, and will include the anterior face of the rectocele and the posterior face of the muscular barrier on each side of the vaginal outlet. These two surfaces are to be brought together by interrupted sutures, as was done on the anterior wall, and we thus dispose of the rectocele. The separated muscles are then to be brought together by special sutures, but it is impossible to explain the operation so that you can understand it fully, without demonstrating it on the subject.

I will state, that after you have been graduated I will be glad to see any of you at the Woman's Hospital in New York. My operating day is Tuesday, at two o'clock. I will then be able to show you every step of the operation.

ORIGINAL ARTICLES.

FOURTEEN DAYS WITH PASTEUR.

BY FRANK S. BILLINGS, D.V.M.,
LATE PATHOLOGIST TO THE NEW YORK POLYCLINIC SCHOOL OF MEDICINE.

THE writer was selected by Dr. H. C. H. Herold, President of the Board of Health of Newark, N. J., and by Dr. Wm. O'Gorman, of that city, to accompany to Paris four boys who had been bitten by a *supposed* rabid dog, in order that they might have the advantage of the preventive treatment of M. Pasteur. As the parents of the children had not sufficient means to send them, Dr. O'Gorman, a gentleman of great benevolence, and enjoying the first position among the practitioners of Newark, resolved that they should be sent, and opened a public subscription which was liberally supported by many benevolent citizens of that city and elsewhere.

The names of these children were, William Lane, fourteen; Austin Fitzgerald, ten; Patrick Reynolds, ten; and Eddie Ryan, five years old. They were bitten on Dec. 2, 1885, and all by the same dog. The wounds of Lane and Reynolds were upon the hands, and under ordinary circumstances would be thought nothing of, but, as is well known, the smallest wounds in case of rabies are even more to be feared than large ones that bleed freely, and again that the percentage of rabies in human beings actually resulting from the bite of a rabid dog has been found to be greater for the superior extremities and the face than for other parts of the body, on account of their being generally unprotected by clothing. The little Ryan boy was bitten quite deeply in the elbow of the right arm, probably by the teeth of the dog, but at the same time the teeth had to penetrate through an unusually thick and felt-like piece of cloth with which the arm of his winter coat happened to be patched at this point. The Fitzgerald boy was not only the most delicate of the four, but was also the most severely bitten; one wound being upon the hand, the thumb having been penetrated very deeply at its base. The other bite was in the gluteal region, and was accompanied by considerable laceration and free bleeding; naturally, the teeth had penetrated through clothing also. Two other children were also bitten by the same dog, but as they were not sent to Paris and were never seen by the writer, but little can be said about them; still, as the whole escapade was an experiment, it is very well that they were left behind as controls, but we must earnestly hope they are in no danger thereby. At about the same time of the day these children were attacked, the same dog was said to have bitten several other dogs, six of which have been discovered and are still in close confinement under veterinary supervision, by order of the Newark Board of Health.

It is greatly to be regretted that so much of hypothesis is connected with these cases as regards the true nature of the trouble with the dog. Indeed, so much contradiction exists, that one can scarcely say what kind of a dog it was, but from all that can be culled from these stories, it seems that it was a middle-sized, short-haired dog, probably with some pointer in his breeding.

The following facts tend to support the hypothesis of rabies:

The dog was certainly in a state of the most intense cerebral excitement. Unlike an ugly, biting dog, he did not stop to tear up or continually bite, or fight with either the children or with the dogs bitten by him. In his frenzy he simply snapped at such living objects as were directly in his way, making a quick snapping bite or two, scarcely stopping to shake the children at all, and then making off; it was not long before he was followed by a small army of would-be-destroyers, and was finally found in a back yard on a shed, trying to gnaw his way through the surrounding board fence. There he was shot, and found his way to the knackers without any autopsy having been made.

This history, however, is sufficient to have warranted the Newark authorities looking upon the case with the utmost suspicion, especially as there had been several genuine cases of rabies canina and hydrophobia in the city and vicinity a short time previously. One was especially instructive, as it illustrates the circumspection with which sympathetic people should avoid demonstrations to stray and suffering curs upon the streets. The lady in question, on passing down a street, saw a small dog by the curb in apparent suffering; she stopped to pat and sympathize with it; the dog snapped at her, merely drawing a little blood from the hand; she died under terrible suffering within two months from that day. The writer knows of two similar cases in the vicinity of Newark, and there had been quite an unusual number of suspicious dogs killed before this accident.

There can be but little sympathy from scientists with the excitement kept up by the papers; still some good will come of it, and, as some assert, only by such a course is it possible to attain much support from the public for the advance of preventive medicine.

The children sailed on the Steamship "Canada" of the Companie Générale Transatlantique, on Wednesday, December 9, 1885, the Company also taking a liberal part in the general benevolence by placing them in the second cabin both to and from Paris. They were treated with great consideration, and all of them showed most pleasing indications of physical improvement. The passage over, as well as the return upon the same ship, was wonderfully pleasant. The "Canada" arrived at Havre December 21st, the passengers being directly transferred to the cars of a special train for Paris, where they arrived at 4 P. M. It is but a matter of simple justice to state that the expedition with which the children were placed under treatment, as well as the saving of the writer and them from any amount of extortion, was largely due to the kind and continued attention of Mr. J. H. Haynie, whose very interesting and complete letters have appeared as from the "Special Paris Correspondent," in the *New York Times*.

The children were at once taken to a hotel, from which they were subsequently removed in order to give them every comfort and care possible. The writer immediately proceeded to M. Pasteur's laboratory, and induced him to place them under treatment that very evening, for it seemed in this case that "time was (not only) money," but might be life as well. Not being a physician, and the operation involved being a surgical one, M. Pasteur does not do it, but has it done by Dr. Grancher, Professor in the University, and the most noted clinician in children's diseases of the present French school. It is scarcely necessary to say that Grancher, like Pasteur, gives his services free of all remuneration so far as this treatment is concerned, save the grand satisfaction of devotion to the salvation of the race from one of the most terrible diseases known to man.

The inoculation, or rather the introduction of the preventive material, is done with the ordinary hypodermatic syringe, the point of inoculation being the umbilical region. The operation is never done on the same side two days in succession. For children under twelve or fourteen years old one-half a syringeful of the fluid is used, for adults nearly the entire contents. The instrument is never emptied completely, one division of the piston being always left. This is probably done so as not to inject the thickest part of the contents, for the material is not filtered. One would expect to see some irritative reaction following the injections, but this does not generally result in the case of the first five or six, but with the last two or three, especially the very last, when the most active virus is used, a distinct hyperæmia at the point of inoculation resulted, which disappears in the course of forty-eight hours. No disturbance of the functional activities followed in any of the children. Whether or not any augmentation in the temperature occurred it was impossible to ascertain from the unsatisfactory hotel conditions under which they were first placed. The number of inoculations varies in general from ten to fourteen, according to the age of the patient and the irritative reaction following the introduction of the stronger virus toward the end of the treatment.

The treatment began December 21, 1885, and ended January 1, 1886; the children were, therefore, inoculated *eleven* times, with the exception of the youngest, Eddie Ryan, who received the virus but *ten* times.

The children sailed from Havre on the evening of January 2, and arrived in New York January 14, 1886, during the whole of which time they were perfectly well.

M. PASTEUR'S DISCOVERIES.

Pasteur assured me that he had never been able to isolate, cultivate, and produce a microbic virus capable of producing rabies in any animal. He assumes that a specific microbe must be present, but neither he nor his extremely able assistant, Dr. Roux, has been able to prove its existence. It seems to me to be one of the failings of Pasteur to have no confidence in the correctness of any work done by others except in his own laboratory. While in Paris a communication was received at the Academy to the effect that Fol, of Geneva, had succeeded in staining a specific coccus in the cerebral tissues of rabid animals, and had cultivated it and produced rabies with it. Whether or not this is correct, I have no means of judging, not having seen the original communication

from Fol, but it was at once asserted to be "impossible" in the laboratory of M. Pasteur, simply because they had not been successful in the same direction.

Such things do not deteriorate from the grandeur of the work already done, which began with the study of the ferments with reference to beer and vinegar, followed by the researches upon the silkworm disease, which have resulted in saving millions of dollars to France. Pasteur next turned his attention to some of the contagious diseases of animals, the first being fowl cholera, then anthrax, rouget, and finally rabies. The first three of these are known to be due to specific microbes. The work of Pasteur has not, however, been that of a bacteriologist in the strict sense, but, filled with the idea that a preventive virus could be made from the elements of such diseased organisms, he has worked more from the methodical standpoint of the chemist than from that of the bacteriologist. Still, with anthrax and fowl cholera he has shown that a virus, or rather two, can be obtained capable of producing a period of immunity for at least one year (anthrax), and for hog cholera, a disease of far more interest to us in America, he has also shown that a virus can be prepared which will give the inoculated animals a certain degree of immunity. With reference, however, to hog cholera, the results are by no means so satisfactory at present as in anthrax. There seems to be a far greater difference in the susceptibility among the different breeds of hogs, with regard to the virus, than in cattle with anthrax. Much may be done in this field yet, for the work of experimentation has ceased at Pasteur's laboratory since the death of the lamented Thuillier, the whole time of those laboring having been given to the study of rabies.

Pasteur seems to have found that every virus *may* be rendered a vaccine under some peculiar manner of treatment; such as the continued exposure to a certain degree of heat for a given time, or to the action of the air, or to desiccation. Bacillus anthracis, for instance, develops spores at a temperature of 37° C., but at over 40° this spore development ceases, there being a very rapid development of very short rods by fission. It has been found that if a spore cultivation of bacillus anthracis is sown in bouillon placed in a thermostat at 43° C., and kept clear, that, notwithstanding the fact that a development of rods occurs, the fluid gradually loses its virulence until, at about the fifteenth day, it causes no effect upon an animal that it would at first kill. Such a bouillon constitutes a primary vaccine against anthrax; one that has been exposed to the same degree of heat for about nine days constitutes a secondary, and a freshly sowed one of one day old at a still lower temperature, constitutes the primary vaccine.

Now here comes the peculiarity of all these artificial vaccines which constitutes fully as great a discovery on the part of M. Pasteur, as that of their practical application, viz.: Each virus retains the same virulency so long as we continue making artificial cultivations in bouillon from it. Having established the fact that a bouillon cultivation of bacillus anthracis had either a negative or very weak action after exposure to a heat of 43° C. for fifteen days, it has been found that, with due precautions against adventitious pollution, we can go on and seed bouillon flocks indefinitely from the primary one, and always have a virus of the same degree of activity. The same is true of the secondary, or stronger, and the tertiary, or strongest vaccine virus. On the contrary, if we take a rabbit and inoculate with this primary or weak vaccine virus, and then go on directly from one rabbit to another, it has been found that in course of time we again arrive at a material having all the characteristics and virulency of the original and natural material.

Another singular fact has been established by Pasteur, with regard to the etiological elements of several diseases. In rabies he has found that when the same material from a rabid dog is carried through monkeys it soon loses its virulency, while if carried through rabbits its activity is augmented. We shall return to this subject immediately. In hog cholera, the infectious elements become ameliorated in virulency when passed through rabbits, but augment when passed through pigeons.

Here, again, we come to the same rule: an artificial cultivation made in bouillon from one of these rabbits or pigeons which killed at a certain number of days, retains that characteristic so long as such cultivations are made, but the moment we again carry it through a series of either animal, it soon follows the course which has been found peculiar to the species used.

I will close this part of the subject with a few remarks of the impression made upon me by M. Pasteur, and about his laboratory, and then return to the consideration of the preparation of the vaccine material used in his anti-rabic inoculations.

M. Pasteur is sixty-three years old. He is a short, thick-set person, about five feet six or seven inches high, with straight black hair, a little sprinkled with gray, and short-trimmed whiskers of the same character. Some few years since, he had an attack of paralysis which affected his left side somewhat, so that the movements of that side are not as free as those of the other. In some ways he reminds one of the late General Grant. He is not much of a talker; has in general rather unemotional features, but has a pair of kindly, dark eyes, with heavy eyebrows. From casual observation or without sufficient acquaintance, under peculiar conditions, one would never be led to think that a man so apparently unemotional possessed a tenderness and emotional sympathy far beyond that of ordinary women. When babes or very young children displayed exceeding fright after the first inoculation, when brought each succeeding day, one did not have to watch very closely to see the pearls of sympathy gather in the master's eyes.

It would be unjust to Pasteur not to enter our earnest protest against an impression that has gained more or less extension over the world, viz., that he is exclusive, that he does not publish his methods and keeps them only for himself and those connected with him in work.

In this regard Pasteur's position has been exactly what Koch's was when connected with the *Reich's*

Gesundheits Amt. Neither of them was in the position of teacher; the former had his laboratory and government aid that he might proceed in a certain line of research which, he had become convinced, would be of immense value to the agricultural interests of the country. Communications have been occasionally made to the Academy, as circumstances warranted, regarding the nature of the work and how it has been done, but it was not Pasteur's mission to teach, and it appears as if he had never had sufficient leisure to write any extended works. But, as he has himself said, "it is all in the *Comptes Rendus*," even to rabies. The same is true of Koch. While in the position mentioned, he was appointed to do certain work in connection with given diseases. The German Government, recognizing the demands of the scientific world, promoted Koch to a professorship in the Berlin University, with the probable result that while an inferior man could have equally well served in that position, the world will suffer in the interference thus made in the work of one of its most noted investigators.

Pasteur, while not the author of vaccination, may be truly styled that of the Vaccine School of Research. Another, which will divide the honors with it, is known as the Bacterial School. Both of them are engaged in the work of Preventive Medicine. The school established by Pasteur is certainly limited in its practical application, while the other, which is more of a Teutonic production, is almost limitless in the application to the prevention of disease. The one is direct in its application, the other indirect. The one is simply practical, the other both practical and philosophical, for the proper application of the teachings of bacteriology to the needs of man, requires the most exact study of all the various phases of sociology, climatology, etc.

THE LABORATORY.

The laboratory of M. Pasteur is situated upon the grounds of École Normale, the entrance being No. 45 Rue d'Ulm. It is a one-story building about one hundred feet long, with cellars under its entire length. One is surprised at the number of rooms, closets, etc., that it contains. In a small wing on the left is the entrance, to the left of which is the private room of the savant. To a person who has worked in the modern laboratories of Germany, that of Pasteur appears to be very parsimonious in its fittings. In fact, no better evidence is needed to support the assertion previously made, that the work done here is more from the chemical point of view than from the bacteriological, than the sparsity of paraphernalia used in the cultivation and study of bacteria. On the other hand, this very fact only goes to place more strongly in view the wonderful character of the presiding genius.

The one great medium of culture here is bouillon. I could see but little evidence which tended to prove that much attention was given to the study of bacteria from the biological point of view and their relation to, or, better, deportment in different culture media. On the other hand, such are the delicacy and exactness of technique that have been acquired by the assistants of Pasteur, that they may soon arrive at comparatively pure cultures in fluid media. As just stated, bouillon is used for almost everything, even where other persons would resort to distilled water, for there are no conveniences here for making the latter.

Pasteur and Chamberland have perfected the most wonderfully perfect clay filtering tubes I ever saw. By the use of these, under condensed air pressure, they can at once prepare water, bouillon, blood-serum, or even saccharine solutions, and have them entirely free from germs or spores of any kind, without recourse to any further sterilization by means of heat; years of experience have proven the correctness of this assertion. The saving of labor thereby, as well as time, is something that cannot well be calculated. These filters should be introduced into this country for domestic use as well as laboratory work, as I am sure that American ingenuity has never produced anything equal to them.[1]

On the ground floor we find first a photographing-room, which is used exclusively by the first assistant, Dr. Roux. Of Roux's photographs of bacteria, no person can have any conception who has not seen them. They are simply wonders of exactness, as much superior in definition and outline to those of other micro-photographers as the diamond is to charcoal. Roux is an entirely different kind of man from Pasteur. The latter is reserved, and one looks in vain for any indication of enthusiasm, in place of which he sees dogged determination. Roux, on the contrary, is one bunch of nervous energy, with no lack of perseverance marked in his countenance. He is a tall, slim fellow, who shows the indications of hard work and overtension in every expression and movement. The grasp of his hand at once expresses to you earnestness and sympathy, and if he finds you educated and interested, there is nothing that he will not do to make clear everything you desire to know.

The second assistant is a graduate of the École Normale, a M. Wasserzug. The name would indicate a German, but he would deny it, and tell you he was an Alsace Frenchman, yet I was pleased to find him utterly free from any dislike of his German neighbors—in fact, he spoke of them with the greatest earnestness, and was especially desirous of hearing everything possible of Robert Koch and his methods. He is a young man, more German than French in energy and character, and it was mostly through his personal attention that I obtained the knowledge I gathered at this laboratory.

As we leave the photographing-room, we pass into one in which we find the monkeys which have been inoculated, and thereby attained immunity from rabies. From their friendliness and good health, one would never realize that each of them had been put through a most trying ordeal, for they have all been inoculated with the most virulent rabid virus. The next room is used for all sorts of operations upon animals. Then comes a hallway from which we go down to the cellar, and also from it into the main laboratory. One of the most striking things one sees is the immense variety of flasks, tubes, balloons, etc., of glass, with tubes extending from them, and necks twisted into almost every imaginable shape. This certainly

[1] See THE MEDICAL NEWS, June 6, 1885, p. 627.

indicates that such experimentation to find the most favorable forms of vessel that can be used to prevent pollution, when the contents are being inoculated, must be very expensive. So it would be were these things all ordered from a glass factory, but here we find a most practical idea, which we should follow here if we ever have laboratories for the same purpose—*i. e.*, one of the servants of M. Pasteur is a glass-blower, and makes almost, if not all, this kind of material used, certainly all of the smaller and more complicated varieties. The light in this building is as perfect as any one could wish, as the rooms have large windows, and the main room has them on both sides.

In the cellar we find a room for the rabbits that are used in producing the rabid virus only; they are all kept in small wire cages, two in each. Artificial rabies in rabbits is not characterized by any of the ferocious symptoms which we have learned to dread in the dog. They do not appear to labor under any cerebral excitement whatever; they do not bite or fight, but simply suffer from a slowly progressing paralysis. Whether they have tetanus or not I do not know, but certainly they do not fall into any spasms on disturbance. In another room we find animals used in the study of anthrax, and so on for hog cholera, etc. As I left, Dr. Roux was beginning the study of material from the so-called enzoötic abortion in cows, a disease which causes much loss to cattlemen all over the world.

The dogs were formerly kept here, but becoming "disturbers of the peace" they have been removed to an especial building on a neighboring street. They are all kept in very securely made iron cages. Here is a fine opportunity to study canine rabies in all its stages and varieties. Upon the same grounds is situated the building in which is manufactured the anti-anthrax virus, which is being called for all over Europe.

One of the best points to be followed, which can be seen here, is, that each servant has but one kind of work to do. The assistants have nothing whatever to do with the preparation of any kind of virus after the methodic has once been completed to Pasteur's satisfaction. They are continually employed in completing some process or opening up new work. One man inoculates all the rabbits for rabies and prepares all the virus to be used in the inoculations; while another makes anthrax vaccine, and another the cultures of hog cholera. I have never seen laboratory work so well systematized or go on with so little jarring, and few men in this country have had better opportunities for judging.

What supports all this? The government of France! For this purpose M. Pasteur at present receives 50,000 francs per year, but from all that I have seen it is very doubtful if this amount fully covers the expenditures, as he is a person who would never stop to think of his own pocket when more means were necessary to arrive at the completion of some object by which his country's interests would be advanced or human suffering lessened.

THE PREPARATION OF THE VIRUS.

Pasteur's studies upon rabies began in the fall of 1882. The first human being to be inoculated was the boy Joseph Meister, on the 7th of July, 1885. The real grandeur of this work cannot well be expressed in language. The intense responsibility, the almost death like pressure which must have weighed upon the brain of Louis Pasteur when he made this, his first experiment upon a human being, can only be appreciated by one who has become acquainted with canine rabies in its terrible violence, and hydrophobia in its unspeakable tortures, and further with the entire details of this preventive treatment, how it has been arrived at; such a person, I say, is the only one that can appreciate all Louis Pasteur has been through.

I do not know that it would not be possible to have brought home some of Pasteur's material; it could certainly have been done by the aid of rabbits on board the ship, but I did not ask for it for just one reason, and that is, that I do not consider either myself or any other person would be justified in trying to inoculate his own species, before he had himself gone through the entire work by which Pasteur has arrived at his present confidence, and by similar and repeated experiments upon dogs, have become as well acquainted with the action of his own material as Pasteur is with his.

It is well known that the saliva of the dog has always been looked upon as the essential medium of infection. It is equally well known to every practical bacteriologist, that no more difficult substance could be taken from which to isolate a specific microbe than this saliva, especially, as is probably the case, if this microbe be a coccus. From his observations of clinical phenomena, Pasteur concludes that the specific elements of rabies are to be found in a pure condition in the material of the great nervous centres, brain, and spinal cord, more easily than elsewhere. Experience has proven the correctness of this conclusion, but it still seems doubtful if we shall not also find the same elements in an equally pure condition in the large salivary glands, on the side and under the jaws, as in the brain. The very fact that this saliva is the usual medium of communication of the disease to other animals indicates this.

I have been told that for his cultivation of the microbe, which he claims to be specific, Fol used the fluid he could squeeze out from the fresh brains of sheep. To my mind, the best and most natural way to obtain a medium for the cultivation of the specific microbe in this case, if one thought he had found it, would be to dissect out the parotid duct on each side of the jaw of a large dog, and have its secretion received in appropriate vessels. I would also use cattle for the same purpose. This material can be sterilized in its natural condition, and also made into a solid medium by the use of gelatine.

However, Pasteur has found the brain-substance to answer every practical purpose; from it he prepares an artificial virus, without any direct knowledge of the existence of a specific bacterium, as is the case in the vaccine we obtain from calves. Looking upon the brain as the chief seat of this material, it was but natural that he should also select that organ as the point of inoculation for his future experiments. The supposition proved correct. Every dog thus in-

oculated from the brain of another rabid dog died in an average period of fourteen days. This fact established, the next step was to find a means of mitigating this material, and a method of using it as a preventive medium.

Not having isolated any specific bacterium, it is evident that the means used in the preparation of the anthrax virus would not be available. Hog cholera had, however, given another indication, which, if followed, might lead to valuable results—*i. e.*, the fluid elements of that disease taken directly from a sick hog, one that had been dead but a short time, if carried through rabbits loses its virulence, but increased in the same when carried through pigeons. It was but natural that Pasteur should desire to try this cerebral extract upon monkeys, as next in kin to man. We can well imagine his astonishment at finding that even the most rabid virus caused no serious disturbance, and that if the inoculations were made through a very short series of monkeys the virus becomes powerless, even upon dogs. Now here he sat upon the apex of a most difficult horn of dilemma. Here was, indeed, a means of preparing a primary rabid vaccine, but where on earth were the monkeys to come from?

This method, self-evidently, had to be given up. Had he only had the microbe isolated and cultivated, and produced this monkey rabies with it, he would have found his preventive virus much sooner than he did.

The monkey not being available, it was but natural that he should turn to that invariable object of vicarious experimental sacrifice, the rabbit. Here he was again struck by a very singular phenomenon. After experimenting for some two years, and using about 2000 rabbits, he satisfied himself that if one inoculates a primary rabbit in the brain with similar substances from a rabid dog, that that first rabbit becomes rabid in just the same time a dog would if treated in a similar manner; the next thing was to discover what would be the result of carrying such a material from rabbit to rabbit in the same manner as had been done with monkeys. This being done with innumerable series of rabbits, it was found that after thus inoculating from twenty to twenty-five rabbits that the rabid material had so degenerated in virulence that it killed each rabbit in seven days. This same material acted in the same manner when inoculated upon dogs. Hence Pasteur could almost have claimed to have produced a new disease out of an old one. Now comes the question, How can this material be diminished in virulence?

The brain-substance could not be handled very well, so that the next step was to try the spinal cord, the most accessible portion being the medulla oblongata. This was found to act exactly as the cerebral substance had done. The next step was to try the effects of heat and cold upon it in a dry atmosphere; the microbes, if present, must thus be deprived of one of the chief essentials to their existence. The dry air was easily found by placing lumps of desiccated caustic potash in the bottom of glass jars. The corks were made to fit very neatly, and were of the best quality. The medullas were then removed with the utmost care to avoid pollution with any foreign material, and hung by a thread attached to the corks in the jars.

The following results ensued: When kept in a cool place, the medullas retained their virulence a long time, which could be increased by filling the glass jars with carbonic acid gas. If, on the contrary, they were kept in a room with a constant temperature of 20° C., it was found that they lost in virulence with each day's action of the dry atmosphere and the surrounding heat, until after, or on, the expiration of fourteen days, a medulla was found which produced no perceptible action upon rabbits or dogs when introduced into the brain.

It was now necessary to discover if each one of these medullæ possessed any constancy of action according to the time they had been thus treated. One can hardly realize the amount of work that had to be done, and of the inoculations that were made before this fact could be considered as established. Finally, it again resulted as in other vaccines under methods of treatment: *that any number of medullæ of approximately the same thickness had the same action upon animals, if introduced into the brain, after having had the same amount of exposure—i. e.*, a canine medulla would cause rabies in a rabbit in 14 days; a super-virulent rabbit medulla would cause rabies in a rabbit in 7 days; after the latter had been taken out and subjected to treatment for about two weeks, all action disappeared. A slight action followed the use of one of 12 days, more of one of 10, and so on more and more until one of 1, 3, 4, or 5 became more and more virulent.

It must be borne in mind that these results were all obtained by inoculating a single animal from a given cord of a certain number of days' treatment.

The next thing to do was to try the effect of the serial introduction each day, or at intervals of a day or two, of a series of three separately treated medullæ from rabbits, beginning with a cord that had been treated for 14 days, and ending with one freshly removed from a rabid animal.

What was the result?

I should like to know what Pasteur's feelings were at the moment when he had found that no rabies followed in his animals. No man can portray them!

Then came the revelation before the Academy; the doubts and sneers; the appointing of a committee to watch and prove: the treatment of twenty-five dogs as a test case; the control experiment with twenty-five others that had not been treated to the bites of rabid dogs; the anxious waiting for time to elapse. Then Victory!

The curtain should be dropped here and the story ended, but it is not. Then followed experiment after experiment until all was as safe as the simplest injection of a harmless material, and then came the tests.

It will be seen from the following statement that the child was daily inoculated with a piece of spinal cord from a rabbit of ever-increasing virulence. The cords were subjected to the action of a dry atmosphere a shorter and shorter period after their removal from the rabbit, until finally a cord comparatively fresh—that is, only one day old—was used.

The boy Joseph Meister. The inoculations began on the 7th of July, as follows:

Date.	Time of inoculation.	Date upon which rabbit was inoculated from which the spinal cord was taken.	No. of days the cord was dried after removal.
July 7	9 A.M.	June 23, 1885	14
" 7	6 P.M.	" 25, "	12
" 8	9 A.M.	" 27, "	11
" 8	6 P.M.	" 29, "	9
" 9	11 A.M.	July 1, "	8
" 10	11 "	" 3, "	6
" 11	11 "	" 5, "	7
" 12	11 "	" 7, "	5
" 13	11 "	" 9, "	4
" 14	11 "	" 11, "	3
" 15	11 "	" 13, "	2
" 16	11 "	" 15, "	1

The method of inoculating rabbits is simply that of ordinary trephining, the instrument being smaller and having the diameter of an ordinary leadpencil.

The fresh medulla is rubbed off with bouillon, as later described, and about two divisions of the piston of an ordinary hypodermatic syringe of fluid injected under the meninges; the end of the kneedle must be curved. The skin is then sutured as in any other case.

At the same time the child was inoculated, another rabbit was immediately afterward inoculated with exactly the same material used on the child. This is done with the virus used on every person inoculated by M. Pasteur in order to keep the experiments under the most exact control. The result is thus reported by M. Pasteur:

The medullas or cords which were removed from rabbits and inoculated on the child July 11, 12, 14, 15, and 16 respectively—that is, which had been desiccated seven, five, four, three, two and one day—all gave positive results when reinoculated upon rabbits in a degree corresponding to the time they had been dried—*i. e.*, the freshest cords caused the appearance of rabies in the rabbits in seven and eight days, while the others gave results later and the driest gave none.

The fresh cords having therefore caused the outbreak of rabies in the regular time, which the most virulent cords from rabbits had previously done, and the same not having caused any disturbance whatever to appear in the boy Joseph Meister, Pasteur concludes "that the boy has not only escaped a future outbreak of canine rabies, but also that the systematic inoculation has so prepared the elements of his body that they were enabled to resist the action of still more virulent rabbit rabies."

This virus from each of the cords is made by taking a small piece about one-fourth of an inch in length and rubbing it up with a glass rod and adding sterilized bouillon, drop by drop, until the fluid and mass are well mixed, and about a tablespoonful of bouillon added. It is not filtered, and some of the substance necessarily settles to the bottom of the glass as a sediment.

The virus is made fresh every day, the glasses containing it being prepared about 10 A.M., the inoculation occurring about 11 A.M. While waiting, the glasses are carefully covered so as to prevent anything falling into them from the air. As no cord is used a second time (that is, as a cord which if used to day would be one that had dried six days, but which if put back again into the bottie would be a seven-day cord, and so on), it is evident that a number of rabbits must be inoculated daily in order to keep up the supply of very virulent cords, according to the number of patients present, and also according to the period of their treatment; newly arrived patients requiring cords that have been dried fourteen days, and older ones those of corresponding freshness.

I have thus endeavored to place Pasteur's method as fully before the readers of THE NEWS as possible. It is easily to be seen that the preparation of such material is not a matter that can be done either by private practitioners, or even at ordinary hospitals.

SOME PRACTICAL APPLICATIONS OF PASTEUR'S METHODS.

Muzzling dogs is powerless to prevent the extension of rabies among them.

The best way to prevent rabies in man is to prevent it in dogs. This can be done in the following manner:

1st. Each State should have a State Laboratory in connection with its Board of Health, in one department of which such cords should be constantly prepared, and the physicians and veterinarians of the State educated in their use on animals.

Every endeavor must be made to discover the microbe of this disease, and an artificial virus from the same, which can be used in the same manner and as trustworthy as that at present used by Pasteur.

2d. The next step is to discover, by direct experiment, how long the immunity from rabies can be trusted to continue in dogs after they have been treated as above described.

3d. Laws must be made conformable to the above, and record books kept in each city. Every dog must not only be inoculated but licensed, certificates of which must be filed with the proper authorities, and presented each year when the new license is applied for.

Experience only can tell the time in which such certificates must expire and be renewed.

4th. All dogs not inoculated must be killed at once.

This is practicable; and only in this way can we do away with canine rabies, and eventually remove all danger of hydrophobia from our citizens.

NEW YORK, January 20, 1886.

IMPACTED GALLSTONE IN THE DUCTUS CHOLEDOCHUS.[1]

BY F. LANGE, M.D.,
OF NEW YORK.

ABOUT the middle of July Dr. Heppenheimer, of this city, sent to me Mrs. B., 37 years of age, married. A previously healthy woman, about six months ago she commenced to suffer with severe pain in her right side, over the region of the liver. Sometimes she suffered so severely that she was forced to cry out. The pain was also located toward her back.

[1] Read before the New York Surgical Society, Dec. 22, 1885.

About one month later jaundice set in, and has since remained. Loss of appetite, vomiting, mostly in the morning, and sometimes of a greenish material. The constant pain has weakened her very much, though her nutrition is not so much impaired as one would expect after such protracted and severe suffering. Her color is of a deep greenish-yellow; skin flabby. The expression of her face I should describe as languid and dissatisfied. She is feverish, and often feels chilly, but has never had a marked rigor; stools light in color; bowels tend to constipation; urine icteric; constant pain in her back; sometimes pain in epigastric region; entire loss of appetite; often nausea. As the principal result of physical examination an enlarged liver presented itself. Fulness from fourth intercostal space down to one inch above umbilicus, and from that point obliquely down to the anterior superior spinous process of the ilium the left lobe seems to be proportionally much enlarged. Four inches to the right of the median line a mass about the size of an orange is felt just below the border of the liver; its position, shape, and resistance make it correspond to an enlarged gall-bladder; other organs apparently healthy.

On the 23d of July a longitudinal incision was made about six inches in length through the external border of the rectus abdominis; peritoneum opened; gall-bladder not adherent to the abdominal wall; its color light yellowish-green. By aspiration about one and a half pints of a rather thin purulent fluid were extracted; toward the end of the aspiration the same showed a more free admixture of pus; microscopically pus-cells and cholesterin crystals were found. The amount of fluid withdrawn was much more than at first seemed probable from the size of the tumor; that proved, of course, a considerable dilatation of the gall-ducts beyond the gall-bladder itself. After turning the patient on her right side, and pulling the now flabby gall-bladder partly before the abdominal wall while interposed sponges secured closure of the peritoneal cavity, a free incision was made into the gall-bladder, from which more fluid escaped. Neither finger nor instruments, curved as well as straight, reached a stone, though the cavity was explored to the depth of about eight inches. After having enlarged the abdominal wound by an incision at right angles to the first, I passed my hand along the lower surface of the liver toward the duodenum, and there was able to distinguish by the touch a hard, round body. In order to get at it with ease, I had to separate the colon from its physiological and pathological adhesions to the lower surface of the liver, and then was able, by gentle pressure and manipulation, to push the stone back into the gall-bladder, whereupon it was easily extracted. Hemorrhage was insignificant on account of double ligature before cutting adhesions, which were most extensive at the lower surface of the gall-bladder. The stone was about the size of a small walnut, oval-shaped, smooth, without facets, consisting of pure cholesterin.

The patient was then again turned on her right side. The bladder was irrigated with a weak solution of boro-salicylic acid; the gall-bladder closed by triple rows of Lembert sutures, and, finally, the abdominal wound sewed up by deep peritoneal and superficial sutures; light dressing of iodoform gauze.

The operation lasted more than two hours, and the patient was in collapse immediately after it, but soon rallied, and in the afternoon had a moderately good pulse, with a temperature of 101°–102°.

The principal features of the following days until her death, which occurred on the morning of the 26th, three days after the operation, were these:

Vomiting, gradually increasing in severity, sometimes with pus; on the second day, with free admixture of blood; no bile. One large clot, about three inches long, looked as though it must have come from the bile-duct; in one place it consisted mostly of fibrin, and was somewhat constricted; the remainder being apparently a more recent coagulum. Microscopical examination showed much columnar epithelium caught in it. Urine became quite scanty, containing albumen and epithelial and hyaline-granular casts, which were not present before. Abdominal pain and tympanites moderate; temperature gradually increasing to 104° on the third day. The fact that the vomit contained no admixture of bile, and the stools, which were occasionally passed, had retained their grayish color, led me to assume that in some way the flow of bile into the gut might be interfered with. I therefore, on the 25th of July, opened the abdominal wound, and finding safe adhesions between the gall-bladder and parietal peritoneum, opened the former, giving exit to a considerable quantity of green, healthy-looking bile. The bad symptoms continued in spite of this, and on the morning of the 26th the patient died, having a temperature of 108.2°; quantity of urine during the last twenty-four hours was twelve ounces, about the average of the days before.

The autopsy made on the same day was only conceded in reference to the abdomen. The liver had, within those few days after the operation, returned to almost its normal size. The whole system of gall-ducts was much distended; the ductus choledochus, which might have admitted a finger, ended with a round lacuna within the walls of the duodenum, where apparently the impacted gall-stone had been located. Several small openings led from here into the gut, which all along the small intestine was filled with a brownish, chocolate-colored material, similar to that vomited during life. The essential points of the microscopical examination, which I owe to the kindness of Dr. Porter, pathologist to the Presbyterian Hospital, were these: "Hepatic cells in a state of granular and fatty metamorphosis, which had completely destroyed their identity. There were also marked biliary pigmentation and slight interstitial thickening. The sections of the liver presented the appearance common to acute yellow atrophy of the liver. Sections of the kidney showed the most advanced stage of acute parenchymatous metamorphosis. The epithelium was swollen and the protoplasm destroyed and replaced by granular particles and fat droplets, the latter predominating. The points of discoloration upon the intestine appeared to be ecchymotic.

"The cause of death in this case may be ascribed to the toxæmic condition produced by the advanced

metamorphotic destruction of the hepatic and renal cells."

I have been, and am still of the opinion, that an acute septic peritonitis might have caused all the above changes, though nothing more of an exudation could be discovered on the surface of the peritoneum than is necessary to account for an adhesive inflammation on the separated parts. There have been, however, cases of a peritonitis septica under observation where the macroscopic changes were either absent or quite insignificant. From a practical point of view the following considerations may be allowed:

1. Would it eventually be preferable, as recommended and done by others in cases of cholecystotomy, first to establish a fistula of the gall-bladder, operating *en deux temps* in order to be as secure as possible against infection of the peritoneum? If then after free opening of the gall-bladder the stone cannot be reached, apparently on account of the curved course of the bile ducts, would it eventually be the safest plan to leave it alone and trust to its final spontaneous perforation into the intestine? In our case, as shown by autopsy, this natural process was already inaugurated. In spite of all possible care and precaution it is very difficult, during an operation lasting several hours, to prevent the entrance of infectious material. I need not to say that antiseptic measures were used to my best knowledge in my case.

2. One might, before opening the gall-bladder, search for the stone by palpating along the cystic and common duct. If found near the duodenum, one could try to dislodge it with the intention of pushing it back into the gall-bladder. If one succeeds in doing so, the operative procedure first mentioned might follow.

3. To excise a gall-stone impacted in the common duct *in situ*, seems to me, on account of the deep situation and inaccessibility of the operating field, and the probable impossibility of preventing the contents of the duct from entering the peritoneum, a hopeless way of proceeding. Should it prove to be impossible to push the stone back or to extract it from above, an artificial communication between gall-bladder and intestine, according to Winiwarter's idea, might come into consideration.

If I were to operate a second time under the same conditions as those above described, I should first puncture the gall bladder, and with a fine needle withdraw as much fluid as possible. I should then try to define the point of obstruction, and, in a case like mine, push the stone into the apex of the gall-bladder. Then I should close off the peritoneum by sutures around the partly protruding gall-bladder, and after that is achieved, open the latter, extract the stone, and not close the gall-bladder until the spontaneous entrance of bile into the gut had manifested itself.

Mr. President: All these questions can only be settled by experience. I purposely omit quoting those valuable contributions which have lately been offered relative to this subject. My case just recorded, through the location of the stone and the difficulty of getting at it, has some peculiarities of its own, and may form, in spite of its unfortunate end, a valuable addition to our present knowledge.

THE ABORTIVE TREATMENT OF BUBO.

By PHILIP F. HARVEY,
ASSISTANT SURGEON U. S. A.

The article entitled "Venereal Bubo," by D. T. Armstrong, Ph.D., M.D., etc., in The Medical News of December 5, 1885, merely refers to the injection of dilute carbolic acid in the abortive treatment of that painful affection, but omits all mention of the method originally described by Dr. Morse K. Taylor, U. S. A., in *The American Journal of the Medical Sciences* for April, 1882. Dr. Taylor, in his paper, cites a number of cases in which his treatment ended in speedy and complete recovery, and for over three years I have treated all cases of bubo that have fallen under my charge in the manner he describes. Having seen no mention of his method in the medical journals, and as some inquiries among my surgical friends show that it is not as generally known and practised as it should be, I am induced to call renewed attention to it by briefly reciting some of my cases.

To save the trouble of referring to Dr. Taylor's original article, I will briefly recapitulate the successive steps of his method: The skin covering the bubo is first chilled with a spray of ether; the enlargement is then grasped between the thumb and finger of the left hand, held firmly, and the point of a hypodermic syringe thrust obliquely into the centre of the gland, to a depth equalling about two-thirds of the narrowest diameter of the tumor. The syringe being charged with an 8 gr. solution of carbolic acid to the ounce of distilled water, twenty to thirty minims are slowly injected. A bag of shot or sand, weighing about three pounds, is then placed on the bubo and held in place by tapes; although in favorable cases this may not be necessary. The stage of the disease at which the injection yields the best results is when the gland has attained a sufficient size to admit of the free infiltration of the injected fluid throughout its structure. At such time, one thorough injection is usually sufficient to effect a cure, and this without the patient foregoing his usual avocation. When the gland is smaller and harder, it may be necessary to repeat the injection once or oftener.

Case I.—In the spring of 1882, Pvt. E., 11th Inf., was affected with double inguinal bubo arising from chancroid. He had been under the customary treatment for some weeks in hospital, and one gland had suppurated, but was not open; the other was large, but fluctuation could not be detected in it. The bubo containing pus was aspirated, and the cavity hyperdistended with carbolic acid solution. Aspiration failed to detect pus in the other bubo, and it was injected with 30 minims of an 8 gr. to ℥j solution of carbolic acid. Marked improvement followed this treatment, and two more injections sufficed to effect a perfect cure.

Case II.—S., colored, servant. Male. Applied to me in April, 1882, for treatment for a recent and hard inguinal bubo. It was injected in the manner described, and the patient was not seen again for three days. The bubo was then injected, and complete cure followed in a few days without further treatment. This man did not lose an hour from his work.

Case III.—Pvt. M., 25th Inf. (colored). Affected with a bubo that had been treated by iodine and poulticing for one month. It was rather large, somewhat soft, and quite painful, and was evidently on the point of breaking down. The man was taken into hospital, put to bed, and treated by the abortive method. Three injections effected a perfect cure. Time under treatment, one week.

Case IV.—Military convict. Treated while in guard house. Single inguinal bubo; cured by two injections.

Case V.—Pvt. D., 17th Inf. (white), was taken into hospital July 6, 1882, with double inguinal bubo. The hospital steward having been instructed in the proper mode of making the injection, was directed to administer it in this case. The patient declined to allow the steward to "try experiments on him," insisting that poulticing was the best method of treatment. On the 7th inst., I injected the bubo in the left groin, which was larger than its fellow, and exquisitely painful, notwithstanding the patient's objections. On the following day this soldier requested me to inject the bubo on the right side. He said the pain was at once relieved in the left bubo, and had not returned. No other injections, however, were necessary in this case, and the patient was returned to duty in a few days afterward.

Case VI.—D. S. G., recruit, 21st Inf. (white). Inguinal bubo; right side. Injected March 21, 1883; returned to duty March 22, 1883.

Case VII.—Pvt. J., 25th Inf. (colored). Admitted to hospital in February, 1883, with large and inflamed chancroid; treated with iodoform. Multiple buboes ensued; they were injected on the 11th, 13th, and 16th. Result, prompt cure.

Case VIII.—Pvt. S. P., 25th Inf., chancroid and right inguinal bubo; recent; no pus. Presented August 7, 1883. Injected bubo, using spray and compress. Kept patient in quarters. August 8th, no pain; swelling less; injected a second time. 10th. Bubo diminishing; again injected. On the 15th, the bubo having not disappeared, it was evident that walking about was keeping up irritation. He was therefore taken into hospital and kept at rest until the 25th, when he was fit for duty.

Case IX.—Pvt. J. W., (white) a prisoner, having just arrived at the post, applied September 12, 1883, for treatment. In his left inguinal region there was a large swelling, soft and extremely painful to the touch, and of red, angry appearance. He was wearing a truss over it, as his physician had informed him that he was ruptured. His truss was removed and he was kept at rest until the following day, when his bubo was aspirated, about eight ounces of thick pus being withdrawn; and phenol solution being afterward injected. On the 17th he was admitted to hospital. On the 22d, the pus was again aspirated, and cavity injected to hyperdistention, the fluid being afterward withdrawn. 23d. Pus having again collected, the bubo was freely opened. The resulting abscess ran its course, although I believe it was decidedly shortened by the phenol injections. The man was returned to duty on the 12th of October.

Case X.—Civilian, tailor; July 15, 1883. Chancroid, followed by bubo. Injected twice; no return after second injection.

The above cases were all treated at Fort Snelling, Minnesota. My notes and practice embrace other cases, but the above seem sufficient to establish the value of the method; in my opinion, it is the best mode of aborting or treating bubo that has yet been described. It may answer well in other forms of glandular inflammation, but as to that I have had no experience.

To insure a full measure of success, the following details should be borne in mind and carried out:

1. The time of election is just prior to suppuration.

2. Rest, a laxative, and reduced diet assist in the dispersion of the swelling, rest being the most important adjuvant.

3. The exact point at which the injected fluid should be delivered in the bubo, is a matter of importance; as also its manner of delivery. These conditions can be satisfied, however, by the exercise of ordinary intelligence and care.

1733 G St., N. W., Washington, D. C.

MEDICAL PROGRESS.

Preparation and Properties of Peptone.—In *The Schweiz. Wochenschr.*, xxiii. p. 381, is given the following description of the properties and method of preparation of peptone: 5 kilogrammes of finely chopped lean beef are placed in a porcelain evaporating dish with 5 kilogrammes of water, 150 grammes C.P. concentrated hydrochloric acid and 20 grammes (Witte's) pepsin; allowed to stand at ordinary temperature for one day, stirring frequently; it is then heated in a water-bath, taking care not to heat the mixture to more than 70° C. for one day. The excess of acid is neutralized by sodium carbonate (requiring about 150–160 grammes). The resulting turbid solution is brought up to 10 kilogrammes, 5 kilogrammes of concentrated alcohol added and then put aside for one day to settle. The precipitate is collected on a strainer, expressed and the liquid filtered. After recovering the alcohol the solution is evaporated to extract consistency, poured on plates and dried. Peptone prepared thus is in brown pieces, quite brittle, yielding when pulverized a yellowish-brown powder, soluble in at least 2 parts of water. The yield is about 4–6 per cent. of the meat used. *Properties:* 1. Peptone should be soluble in 2 parts of water; the solution is not gelatinous, and becomes turbid on adding 5 volumes of absolute alcohol; the addition of more water makes a clear solution. 2. A 10 per cent. solution does not become turbid either at an ordinary or elevated temperature on adding nitric acid, acetic acid, ferrocyanide of potassium, or saturated solution of sodium sulphate. 3. Picric acid produces yellow—tannic acid, ash-gray flakes. 4. Sulphate of copper and caustic potash produce a violet coloration. 5. It should yield not more than 2 per cent. of ash when incinerated. 6. If to 20 drops of a 1 per cent. solution of peptone 5 drops of a 10 per cent. solution of calcium bichromate are added, no turbidity is produced; if the mixture becomes turbid, it proves the presence of at least 5 per cent. of glutinous matter. The solution of bichromate of calcium (Freire's test) is made by dissolving

5 grammes of crystallized chromic acid in 25 grammes of water, gradually adding 2 grammes of pure calcium carbonate; after effervescence the solution is diluted to 60 c.c. and filtered through glass-wool. Owing to the rapidity with which peptone is decomposed, it is not advisable to keep it in liquid form.—*Amer. Journal of Pharmacy*, Jan. 1886.

Dangers of Nerve-stretching.—In an elaborate original investigation from Mierzejewski's laboratory, Pauline Tarnowski records the results of an examination of the spinal cord in thirty-six rabbits, in which the sciatic nerve had been stretched in varying degrees. The amount of stretching was estimated from the weights employed—the maximum being eleven pounds. The examination of the cord was made at periods of from twenty-four hours to six months after the operation.

After slight stretching of the sciatic there was an evident hyperæmia of the posterior column of the cord on the same side. Intense stretching was followed by capillary hemorrhage in the posterior column, with secondary sclerosis and atrophy. After extreme traction upon the sciatic, capillary hemorrhage in the corresponding side of the posterior column could be traced to the cervical region.—*Centralb. f. klin. Med.*, December 5, 1885.

New Method of Preparing Fehling's Solution.—M. Schmiedeberg uses mannite in place of Rochelle salt in making Fehling's solution. He claims that the addition of mannite insures stability to the solution. His formula is as follows: Dissolve 34.632 grammes of crystallized copper sulphate in 200 c.c. of water; to this solution is added a solution of 15 grammes of very pure mannite in 100 c.c. of water and 480 c.c. of solution of caustic soda (1.145), and, lastly, sufficient water to make 1 litre.—*Amer. Journal of Pharmacy*, Jan. 1886.

Odorless Iodoform.—Oppler has accidentally discovered that coffee masks completely the odor of iodoform. The roasted coffee is finely pulverized and added to the iodoform in the proportion of from thirty to fifty per cent.

The following formulæ have been given:

Iodoform	2 parts.
Pulverized coffee	1 "

Mix.

Iodoform	3 parts.
Vaseline	30 "
Pulverized coffee	1 "

According to Gillette, one hundred parts of iodoform may be rendered inodorous by the addition of one part of sulphate of quinia, and three parts of powdered wood charcoal.—*Revue de Thérapeutique*, Dec. 15, 1885.

Unilateral Œdema.—A case is reported by Dr. Bassi in the *Rivista Inter. di Med. e Chir.*, in which an hysterical young woman presented the curious phenomenon of an unilateral œdema that appeared with each menstrual period. There was no other derangement of general health, although the patient is described as delicate. The œdema was absolutely limited to the right half of the body, but there was no alteration in the color, the temperature, or the sensitiveness of the two sides, although less irritation was necessary to produce reddening of the skin on the right side. Concurrently with this temporary œdema there were signs of congestion of the lung on the same side, and the right ovary was painful. Complete anæsthesia of both corneæ and of the fauces was observed.—*Lancet*, Jan. 2, 1886.

Diuretic Mixture for Gout.—J. Mortimer Granville, in his recent work on *Gout in its Clinical Aspects*, discards the usual diuretics as irritant, the indication being to "flush," not to stimulate the kidney. For this purpose the most available drugs are ammonium chloride and potassium chlorate. At the same time the decomposition of the sodium urate in the blood may be attempted, and to this end Dr. Granville considers iodine best adapted, exhibiting it with the salts and glycerine, as exemplified in the following formula:

℞—Ammonii chlor.	ʒiv.
Potassi chloratis	ʒij.
Tinct. iod.	♏cxx.
Glycerini	ʒiss.
Aquæ	ad ʒxvj.—Misce.

F. Mistura, cujus sumantur cochlearia duo magna quartâ quâque horâ et aquâ.

Muscle-grafting.—The following conclusions are presented by Dr. Salvia (*Gazetta degli Ospitali*) as the results of his experiments in muscle-grafting.

1. It is always possible to transplant a portion of muscular tissue from one animal to another, differences of species having no effect upon the definitive result of the operation.

2. In order that the muscle added shall become united by first intention, it is necessary that the portion grafted shall exactly fit the wound into which it is introduced, and that the strictest antiseptic precautions be instituted.

3. At the point of union there is developed new muscular tissue with no trace of a cicatrix.

4. The added muscular elements gradually lose their special anatomical peculiarities and so thoroughly acquire those of the animal upon which they are grafted, that after a certain time microscopical examination reveals no point of difference.

5. Muscular function is resumed in a relatively short space of time.—*Revue Médicale*, Nov. 14, 1885.

Pulse Variations in Health.—Bleuler and Lehmann record a series of experiments made upon themselves with a view to determining the results of certain every-day procedures upon the pulse.

The experiments were made in bed, during the morning hours, the pulse was counted for a full minute upon each occasion, and all the accessary conditions carefully noted. The results were as follows:

Drinking warm water or tea increased, while cold drinks diminished the pulse frequency. Application of heat to the skin, effected by additions to the bedclothing increased pulse frequency, which was decreased by partial exposure of the body surface. The difference amounted to from ten to fourteen beats per minute, and the effect endured for from thirty to forty minutes.

During twenty-four hours of fasting, quietly spent in bed, no changes in the pulse frequency were noticed.

Mental activity—in the form of light reading—as a

rule slightly reduced the cardiac activity, and in no case increased it.

Various gastro-enteric sensations—those of heat or pressure in the stomach, nausea, the sensation of slight intestinal tension, especially in the rectum—all increased the frequency of the pulse.

A similar effect was produced by the ingestion of sodium chloride or sodium sulphate, and explained by the fact that these salts produce the sensations in question.—*Centralb. f. klin. Med.*, December 5, 1885.

Etiology of Gout.—In a work which has just appeared on *Gout and its Relations to Diseases of the Liver and Kidneys*, Dr. Roose thus summarizes the causation of the attacks of gout:

1. Uric acid, in the form of sodium urate, is the *materies morbi* of gout.

2. The deposit of sodium urate in the joints is the cause of the gouty inflammation.

3. This substance is produced in excess, as a result of the imperfect transformation of albuminous substances.

4. This imperfect transformation is for the most part due to functional disorder of the liver, or to excessive supply of nutritive materials, or, as often happens, to a combination of these causes.

5. So long as the excess of uric acid is eliminated by the kidneys, decided attacks of gout may be absent; but the symptoms above described as pertaining to the uric acid diathesis are liable to be present.

6. The kidneys are apt to become *secondarily* affected, owing to the irritation set up by excess of uric acid and other products of defective metamorphosis, and by deposits of urates. Primary disorder of the kidney is not a necessary factor in the production of gout.

7. In the majority of cases of chronic gout, increased production of uric acid is associated with defective elimination by the kidneys.

8. The symptoms of nervous disorder in gout are due to the action of the *materia peccans* on the nerve-centres.

The Effects of Tobacco.—In a recent original investigation (*The Physiological and Pathological Effects of the Use of Tobacco.* Phila., P. Blakiston, Son & Co., 1885), which has received the Fiske Fund Prize, Dr. Hobart Amory Hare, of Philadelphia, thus summarizes the results of his experiments upon the effects of tobacco.

1. Tobacco smoking does not decrease the urine eliminated, but rather increases it.

2. Tobacco does retard tissue waste.

3. Tobacco and its alkaloid cause convulsions in the primary stage of the poisoning, by depressing the reflex inhibitory centres in the cord.

4. It causes the palsy of the second stage, by paralyzing (*a*) the motor nerve trunks, (*b*) the motor tract of the spinal cord.

5. That the sensory nerves are not affected by the drug.

6. That nicotine contracts the pupil, by stimulating the oculo-motor and paralyzing the sympathetic, this action being peripheral.

7. That nicotine primarily lowers the blood pressure and pulse-rate; (*a*) secondarily increases pressure and rate; (*b*) thirdly decreases pressure.

8. That the primary lowering of pressure and rate is due to pneumogastric stimulation, associated with vaso-motor dilatation.

9. That the secondary stage is due to vaso-motor constriction and pneumogastric palsy.

10. That the third stage is due to vaso-motor dilatation returning.

11. That death in poisoning from this drug is due to failure of respiration, the action of the drug being centric.

12. That the blood corpuscles are broken up and crenated by the action of the poison.

13. That in death from nicotine poisoning the blood shows changes in *spectra*.

14. That death can be brought about by the cutaneous absorption of nicotine.

15. That tobacco in moderate amounts increases intestinal peristalsis, and in poisonous doses produces tetanoid intestinal spasm.

16. That the liver seems to destroy the poison, although this destruction is participated in by any set of capillaries in other parts of the body.

17. That tobacco smoking increases pulse-rate and decreases arterial pressure.

Tendon-grafting. — MM. Fargin and Assaky have reported before the Société de Biologie the results of their experiments on the grafting of tendons.

Under rigid antiseptic precautions, the transplantation of one inch of tendon has succeeded, not only in animals of the same species, but between different species.

The animals operated upon were dogs, sheep, rabbits, and birds.—*L'Union Médicale*, Dec. 17, 1885.

Potassium Salicylate in Acute Rheumatism — Dr. E. L. Miller, of Eaton, N. Y., recommends the use of the potassium instead of the sodium salt of salicylic acid in acute rheumatism. He claims that the potassium favors the elimination of the worn-out albuminoid products which fall short of being converted into urea in the body; he has used this salt when the stomach refused to tolerate the sodium salt.—*Cincinnati Med. News*, Dec. 1885.

Pilocarpin in Puerperal Convulsions.—Dr. G. T. M'Keough describes three cases of puerperal convulsions in which pilocarpin was exhibited, and draws the following conclusions in regard to the use of this drug:

"When the coma is profound, and has almost extinguished the action of the reflex centres, pilocarpin is a dangerous agent, on account of the impossibility to the patient of getting rid of the enormous quantity of bronchial secretion and saliva which floods the respiratory passages; but in those cases in which the physician is called before the patient has many convulsions—when the poison has not suppressed entirely the action of the reflex centres—when the patient is partially conscious, probably restless, and moaning, or when convulsions have not occurred, but seem imminent,—it is my conviction that we have in pilocarpin a most valuable adjunct in the treatment of this dreaded disease."—*Canadian Practitioner*, January, 1886.

Alcoholic Paralysis.—In the current number of *Brain*, Prof. Dreschfeld has some interesting further ob-

servations on alcoholic paralysis. He has found that Magnus Huss, who is generally credited with having been the first to describe a paralytic form of chronic alcoholism, was preceded by thirty years by Dr. James Jackson in the United States. The latter wrote in 1822. Dr. Dreschfeld has clinically divided this affection into two groups—alcoholic ataxia and alcoholic paralysis—a classification followed by Lowenfeld, Moëli, Schulz, Krücke, and Strümpell. Alcoholic paralysis is a multiple peripheric neuritis.—*British Medical Journal*, Jan. 9, 1886.

Physiology of the Second and Third Stages of Labor.—Schröder, in the *Zeitschrift f. Geb. u. Gynec.*, xi. 2, presents the following conclusions regarding the processes involved in the second and third stages of labor:

During the stage of expulsion, the energetic action of the abdominal muscles is very essential, and, therefore, narcotics, since they calm excitement and diminish pain, are the best promoters of labor. Ergot and its preparations are, as a rule, contraindicated, since the muscles of the uterus contract of themselves sufficiently. During the third stage of labor it should be remembered that the mechanism through which the placenta becomes detached and is expelled from the uterus is a precise one, whilst the expulsion of the placenta from the vagina is not. The control of the uterus by means of the hand after the birth of the child is, therefore, unnecessary. The placenta will, normally, be soon expelled from the uterus through its contractions, without much hemorrhage. We know that this has happened when the uterus becomes smaller and its lower segment swells out over the symphysis. Then by simple manual pressure, above the placenta in the neighborhood of the contraction ring, we may easily, and without danger, completely expel the placenta. In typical cases, the rational and best method of conducting the third stage of labor is to wait until the placenta has been expelled from the uterus, and then resort to manual pressure. When the placenta is expelled after the manner described by Duncan, then the hemorrhage is apt to be greater, and manual pressure not so effective or simple, since the upper border of the placenta often remains for a time attached at the fundus.—*Am. Journal of Obstetrics*, January, 1886.

The Administration of the Hypophosphites in Powder.—Dr. E. C. Morgan, of Washington, states that practitioners frequently encounter patients in whom the ordinary saccharine preparations of the hypophosphites cause serious gastric disturbance, loss of appetite, and interference with nutrition. Individuals suffering from diseases in which hypophosphites are indicated often possess an intolerant digestive apparatus, thus rendering the administration of syrups questionable and occasionally impossible. The writer has, for these reasons, long been accustomed to prescribe sodium, potassium, calcium, iron, and other hypophosphites, in the form of powder, taken dry or stirred in wine, whiskey, brandy, milk, or water. Some of my professional colleagues have doubtless employed these salts in powder and it is for the purpose of directing more general attention to the subject that I write this article.

The therapeutic advantages resulting from the combination of pepsin and various salts of the hypophosphites are apparent, my attention being first called to the fact by Mr. J. S. Tyree, of our city.

The formula can be varied to meet special indications; but a most serviceable combination is as follows (pulv. hypophosphitum cum pepsino (Morgan)):

℞.—Calcii hypophosphitis	. .	5 parts.
Sodii hypophosphitis	. . .	5 "
Ferri hypophosphitis	. . .	2 "
Mangani hypophosphitis	. .	1 "
Pepsini (Boudault's neutral)	.	8 "
Sacchari lactis	. . . .	4 " —M.

This powder should be finely ground and kept, as well as dispensed, in glass. It can be prescribed in bulk, one-half teaspoonful representing about fifteen grains, the adult dose. The preparation is to be taken three times daily, after eating, and preferably in milk.

Lactopeptine, ingluvin, or scale pepsin, may of course be substituted for the neutral pepsin of Boudault, which latter, after repeated trials, I prefer.—*Maryland Med. Journal*, January 16, 1886.

Ammonia in Anthrax and Carbuncle.—Dr. Leonidas Avendano, in a paper read before the Union Fernandina, a Lima medical society, testified to the great value of ammonia in anthrax and "carbunculous diseases." Indeed, he expressed his opinion that it "is a specific, and that it should be the only drug used." In cases of malignant pustule, he advises that after an incision has been made, some drops of the officinal solution of ammonia should be introduced into the wound with the hope of destroying the bacilli there, and of the ammonia finding its way into the circulation before the bacillus does, and thus converting the blood into a fluid in which the parasite cannot multiply. In addition, some ammoniacal salt, such as the acetate, should be given internally, and on the slightest suspicion of general infection resort should at once be had to intravenous injections of ammonia, in doses of ten drops of the officinal solution diluted with an equal quantity of distilled water. In cases of malignant œdema and carbunculous fever, too, "the microbe should be attacked directly in the blood, ammonia being injected into the circulation." The author detailed several cases in which immediate improvement and ultimate recovery had taken place in patients apparently moribund by the use of repeated ammoniacal intravenous injections. He concluded by claiming for Peruvian medicine the honor of having suggested and proved the value of intravenous medication in no less than four different diseases: Dr. Leno Alarco having first injected chloral in tetanus, and ammonia in septicæmia or purulent infection; Drs. Armando Vélez and F. P. del Barco having employed capsicum injections into the veins of yellow fever patients; and Dr. Néstor Corpancho and himself having originated the treatment above described in carbuncle. —*Lancet*, Jan. 9, 1886.

Suppository for Hemorrhoids.—Martin recommends the following formula for use in cases of hemorrhoids:

Antipyrin	. . . . . 38 grains.
Cocoa butter	. . . . . 150 grains.

For five suppositories: two or three every twenty-four hours.—*Revue de Thérapeutique*, Jan. 1, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 23, 1886.

PASTEUR'S RESEARCHES IN HYDROPHOBIA.

DEEP interest has everywhere been excited by the announcement of the results which Pasteur has recently obtained in reference to the prevention of hydrophobia by inoculation, and in the absence of full and authentic statements of the methods employed and results obtained, the press has been teeming with crude and unreliable accounts and criticisms, favorable and unfavorable, of the work done in Pasteur's laboratory.

We have the pleasure of laying before our readers, this week, a full and thoroughly accurate report of M. Pasteur's methods and results from the pen of Dr. F. S. Billings, of New York, who took four of the bitten Newark children to Paris to be inoculated for the prevention of rabies, and placed them under the care of Pasteur, and he has thus enjoyed exceptional opportunities for studying his methods and for obtaining full information concerning his researches on this subject.

Fortunately for the accurate estimation of the efficacy of Pasteur's inoculations, two children who were bitten by the same dog were not taken to Paris, and, with several dogs which were bitten at the same time, are also now under close observation, and constitute a valuable control experiment, the final result of which will be watched with eager interest.

The practical conclusions to which Pasteur's researches so far tend, are that dogs should be subjected to inoculation for rabies and thus rendered harmless, and that those which are not rendered rabies-proof should be put beyond the reach of doing harm.

EMMET'S OPERATION FOR VAGINAL PROLAPSE.

A GRACEFUL compliment was paid to one of the most eminent of the alumni of Jefferson College by an invitation to give a clinical lecture in the College Hospital. Nearly two score years have passed since Dr. Emmet entered Jefferson College as a student; since graduation he has attained an eminence such as few in the profession reach, he has done a very large amount of original work in gynecology, and his success brings honor to the institution in which he received his professional training. He was greeted by the large class of Jefferson College, between five and six hundred, by some students from other colleges, and many members of the profession.

Our readers will find in this number of THE NEWS an authorized report of his lecture, which was a clear exposition of some of his original methods of treating certain lesions of the neck of the womb, of the vagina, and of the pelvic floor. We do not propose any extended or complete review of the lecture; still less shall we attempt any criticisms of his operations, but we may say a word or two as to some of his statements, or theories and reasoning, for while in hearty agreement with his practice, we cannot always accept his explanations.

Dr. Emmet states that he does not believe a woman can give birth to her first child without more or less laceration of the cervix. In opposition to this statement we might refer to a case under our own observation, where a woman five years after her first and only labor had a cervix and os precisely like those of a nullipara. Moreover, if one will turn to page 103 of Tarnier's work, he will find that this distinguished obstetrician states that in two or three instances of women who had each borne one child, he found the os uteri presenting the same characters as in the nullipara, and that he has even met with a subject in her third pregnancy who presented to the touch a neck identical with that of a primipara. Evidently there was no laceration of the cervix in any of these cases.

Dr. Emmet regards his operation for the restoration of the pelvic floor as reuniting torn fascia, and that narrowing the vagina, in cystocele or in rectocele, is a misnomer. First, as to the last statement: We cannot see that if A, B, and C represent three parallel spaces, and we bring A and C together, crowding B completely out, there has not been a space eliminated. Now this is just what is done when two parts upon the sides of the anterior wall of the vagina are brought together over the median line, and there made to unite, as in Emmet's operation for cystocele. To say that the vagina after the operation is no smaller than it was before the birth of a child, is no explanation, for the vagina during labor is immensely enlarged, and probably has never returned to its original condition, and so the surgeon takes away redundant tissue that nature has failed to re-

move. Moreover, after giving birth to a child, a woman, no matter if labor and lying-in be perfectly normal, never has a vagina as small as she had before. If a vagina can be enlarged, why cannot it be lessened? If it cannot be expanded, why cannot it be contracted, or narrowed? Referring again to the letters just used, A and C were separated from each other, but they are now united, and we naturally ask where is the interval that separated them? We are answered that only "redundant tissue" was removed, just as a woman takes "a plait in her dress if it was too large for her." Supposing the dress to be a hollow cylinder, its diameter is surely lessened when the pleat is taken, and so, to our thinking, the vagina is certainly narrowed when two distant surfaces upon one of its walls are brought and kept together.

Now as to whether Emmet's operation—he has originated so many that the one referred to must be specified—designed to restore the pelvic floor does this by uniting torn fascia, we think admits of doubt. We have been struck with the force of some of Budin's remarks in reference to this point in his paper upon physiological and pathological contraction of the levator ani in the female, published in 1881. He states that the comparison of a purse closed with a cord is more easily comprehended with retractile and contractile muscular fibres than with the fibrous tissue of fascia. "One understands more readily, also, the great distention the bands which encircle the vagina can undergo at the time of labor without being ruptured, if their resistance is due not to fascial tissue, but to muscular fibres." In one word, according to Budin, it is the muscular fibres of the anal levator which are torn in some cases of labor, and not fascia. Hence the operation of Emmet restores the former to their integrity. Now that the anal levator has a most important influence in physiological narrowing of the vagina is a demonstrated fact, and hence, if its fibres are torn, the vagina is necessarily enlarged; while, if restored, we must believe that the vagina is narrowed by the operation.

One word as to the restoration of posterior displacements of the uterus, so often observed after an operation for a tear in the neck of the womb. The explanation is found chiefly, we believe, either in some inflammation of the utero-sacral ligaments, causing permanent contraction, or, remembering the name *retractores*, given to these ligaments, we believe, by Luschka, and that they contain a notable amount of muscular tissue, and too, as the researches of Bayer (*Morphologie der Gebarmutter*) show that they contribute largely to the formation of the muscular tissue of the neck and of the lower part of the body of the uterus, in the operation uniting torn muscular structure, and thus restoring to these retractors their original power.

THE TREATMENT OF PROFUSE HÆMOPTYSIS.

PROFUSE hæmoptysis is most frequently met with in chronic phthisis and in erosion of the trachea or bronchi by aneurisms. The initial hemorrhages of phthisis are rarely profuse, and in the stage of ulceration and softening we do not often meet with very free bleeding. Fatal hemorrhages in phthisis usually result from the bursting of small aneurisms of the pulmonary arteries in the walls of cavities, or from the erosion of mural or trabecular vessels which have not undergone the obliterative arteritis which usually precedes their destruction. Where a patient has died suddenly after a free hemorrhage, one or other of these conditions is almost invariably found. In most of the cases suffocation, rather than actual loss of blood, is the immediate cause of death.

A paper of DR. SAMUEL WEST, on the treatment of profuse hæmoptysis, recently read at the Medical Society of London, led to an interesting debate, in which the principles which should guide the practitioner in this serious emergency were fully discussed. Rest and quiet were naturally insisted upon, and the beneficial effect of opium to allay restlessness and excitement was referred to by several speakers. By some it was also regarded as hæmostatic. As in the majority of these cases a vessel is divided or open, not much benefit can be expected from drugs. Dr. West held that the belief as to the use of vascular constringents in pulmonary hemorrhage is based upon an incorrect theory of its pathology. Ergot, he thought, of doubtful value, as it constricts vessels smaller than those from which the bleeding comes. T. H. Green, and the President, Dr. Ord, thought that ergot is of benefit in reducing the blood-pressure. Oil of turpentine was the only other drug which seemed to be in favor with the speakers.

In these cases we have to deal with conditions precisely similar to those which exist in other parts of the body when a vessel is eroded or an aneurism is bleeding. The hemorrhage, if not immediately fatal, is checked by the contraction of the vessel and the clotting of the blood, which are greatly aided by the reduction in blood-pressure caused by the bleeding. Here we have a clue to the rational method of treating such cases. Unfortunately, the arteries from which the bleeding takes place are usually too far diseased to contract much, and we know of no drug which has the power of increasing the coagulability of the blood; but we can influence powerfully the blood-pressure, and so aid the clotting. We have known a bold venesection to check obstinate hæmoptysis in a plethoric man, but this measure is rarely to be practised in the cases under consideration. Other means must be resorted to, of which purgation is the most efficient, by dilating the abdominal vessels, and lowering the vascular tension in other parts. The same effect may be produced

in the vessels of the skin by amyl nitrite, the use of which was suggested by several speakers. Cardiac depressants, such as antimony and ipecacuanha, also influence the blood-pressure, and are thought valuable by some physicians. But, after all, the bleeding is probably the most efficient aid in reducing the blood-pressure and favoring coagulation at the orifice, and we may truly say, in some cases, though it sounds paradoxical, that if hemorrhage does not kill by suffocation, it may save.

The not infrequent recovery from sharp hæmoptysis in cases with pulmonary cavities, teaches us that the bleeding is often controllable even when a vessel or an aneurism of considerable size has given way. Rest, quiet, and a restricted diet, with free purgation and opium to allay the restlessness and cough, are measures the usefulness of which we can heartily endorse; but in these profuse hemorrhages we place little reliance on ergot, turpentine, or other hæmostatics.

THE INTERNAL USE OF VASELINE.

ATTENTION has been attracted to the effects of vaseline and allied hydrocarbons, when taken internally, by the recent decision of the Minister of Commerce in France that the introduction of these bodies into articles of food constitutes a fraud, and as such is indictable. The wisdom of this decision is made evident in the report of the French Consulting Committee on Public Hygiene on "The prohibition of the use of vaseline, petroleine, neutraline, and every other kind of similar products in the fabrication of cakes and of alimentary substances in general.

"Vaseline, not being liable to turn rancid, is fraught with serious danger to the consumer, who, unwarned by the smell of the age of the cake, runs the risk of purchasing pastry, the eggs used in which have already become tainted, and he only becomes aware of it when the pastry is brought under the control of the gustatory organs."

Apart from this, however, the question of the harmfulness of vaseline and its congeners is dependent upon two other considerations: first, whether it is intrinsically poisonous; and second, whether it is in any degree digestible.

In the first regard the evidence is negative. The lighter petroleums are notoriously toxic, but the heavy, residual "mineral oils"—in reality, soft paraffins—are entirely non-irritant even when applied to raw surfaces, and there is no proof that they are absorbed under these conditions. DUBOIS, of Paris, in the *Gazette Hebdomadaire*, of Nov. 27, 1885, has shown that in animals the ingestion of large quantities of vaseline is followed by no toxic symptoms whatever.

The question of the digestibility of vaseline is most important in regard to its introduction as a component in cooked articles of food. If it be digestible, as intimated by Dubois, then its presence is not likely to render such articles more irritant than similar foods containing butter or lard. If, on the contrary, it be indigestible, it will, when present in cooked foods as a substitute for the organic fats, form around the particles of such food a thin but absolutely resistant pellicle, with the result of rendering the food itself indigestible, and therefore, to a greater or less degree, irritant in its entire transit through the digestive tract.

The first study of this phase of the subject was made apparently by RANDOLPH, of Philadelphia, whose paper appeared in the *Proceedings of the Academy of Natural Sciences of Philadelphia*, in 1884, and who, during eight days, took daily one-half ounce of commercial vaseline. Digestion was in nowise altered, and no appreciable results ensued. Thereupon, to each of two healthy adults was given, in the course of forty-eight hours, one ounce of vaseline, and their feces for three days from the beginning of the experiment were collected, dried, and extracted with petroleum ether. With a slight allowance for incompleteness in extraction, the vaseline ingested was, in each case, recovered in its totality, showing that it had passed through the intestine unabsorbed and unchanged. The same writer, in a later communication in the *Therapeutic Gazette*, of Nov. 1885, states that he has utilized his previous observation by administering vaseline to a number of persons suffering from diarrhœas of irritation, with very satisfactory results. The drug in question, in view of its blandness and incapacity for absorption, probably acted as a soothing application to the irritated mucous surface of the entire bowel. The earlier observations of Randolph receive confirmation in some recent statements by JUNKER, which appear in the *London Medical Record*, of Dec. 15, 1885, and there is a reasonable hope that the method here indicated may prove of service in the treatment of enteric inflammation.

OPERATION FOR IMPERFORATE HYMEN.

THE best method of operating in vaginal atresia, whether from imperforate hymen, or from other cause, is still unsettled, particularly as to the immediate or the gradual evacuation of accumulated menstrual fluid, and as to washing out the uterus if rapid evacuation be used. As remarked by Barnes, a few years ago in a discussion upon the subject before the London Obstetrical Society, fatal cases do occur now and then, no matter which plan may be pursued. It is probable, however, since antiseptics have taken so important a place in therapeutics, and are so generally used in the operation referred to, that its mortality will be lessened. Nevertheless danger may come from the antiseptic itself, as suggested by the history of a case recently reported to the *Societe de Chirurgie* of

Paris, and which we find published in the *Journal d'Accouchements*, of December 30th.

A girl twenty years of age, had for a year suffered from severe abdominal pains; she had never menstruated, and emmenagogues were given her without effect. Upon abdominal examination a tumor was found reaching nearly an inch above the umbilicus; at the vulva a violet-colored tumor, formed by the thinned and distended hymen, was found. The patient was anaesthetized, and a small antero-posterior incision was made into the imperforate hymen, this incision was afterward increased in size, and a transverse one made; gentle compression through cotton wadding upon the abdomen was made, and the liquid evacuated in three-quarters of an hour. A tube was placed in the vagina, and a two thousandth solution of corrosive chloride used to wash out the vagina; these corrosive sublimate injections were continued until the fifth day, when a slight mercurial stomatitis being manifested, they were substituted by a solution of carbolic acid. The patient promptly recovered.

M. BERGER, the reporter, recognizes the dangers that may occur from rapid evacuation in certain cases of menstrual retention, but these cases can be known in advance by the fact that the distended tubes are discovered by abdominal examination, presenting fluctuating tumors outside of the median line.

The fact that this patient suffered from mercurial poisoning, though this was only slight, proves that the normal vaginal mucous membrane has greater power of absorption than has usually been attributed to it, and suggests the importance of using weaker solutions of the corrosive chloride, especially if intra-uterine as well as vaginal injections are made.

In the discussion of the subject by the Society, M. Lucas Championnière condemned the use of carbolic acid solution injections, fearing absorption, because of the solution coming in contact with such an extensive surface, and preferred iodoform as an antiseptic. Gillette suggested that to prevent reunion of the lips of the incision, the latter should be made by the thermo-cautery. Of course, when this is done, immediate rather than gradual evacuation of the menstrual fluid necessarily occurs.

It is questionable whether anæsthesia is advisable, when, as in Berger's case, a tense, thin hymeneal membrane is to be incised or punctured, for the operation cannot be painful. Further, the history of the case, prior to the operation, suggests the folly of giving emmenagogues in a girl who had so long passed the age, and had the development of puberty, without first ascertaining whether there was not a failure in menstrual excretion, rather than of secretion, and the case, therefore, one in which such medicines could accomplish no good and might do much harm.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January 4, 1886.

THE PRESIDENT, W. R. BIRDSALL, M.D., IN THE CHAIR.

A CASE OF SOFTENING OF THE CORPORA STRIATA, WITH SPECIMENS.

DR. J. C. SHAW related the case, that of a gentleman thirty-eight years of age, whom he saw for the first time in July, 1883, in consultation with Dr. Fuller. The patient was a large man, healthy in appearance. About a month previously he had an attack of hemiplegia on the right side, with very temporary loss of consciousness. When Dr. Shaw saw him the arm had entirely recovered, but there was still dragging of the leg. The tendon reflex of that side was exaggerated. There had been no premonitory symptoms except that for six months previous the patient had at times been exceedingly irritable. He denied having had headache, or syphilis, and claimed that if it were not for the paralysis of the leg he would be in perfect health. At this time Dr. Shaw was in some doubt regarding the nature of the lesion; the diagnosis seemed to lie between cerebral hemorrhage and a possible meningo-encephalitis. Against cerebral hemorrhage were his age and the dragging of the foot, the toe scraping the floor; and about the only point which favored meningo-encephalitis was mental irritability. The patient would take no medicine except cathartics.

Dr. Shaw saw him again in consultation in June, 1884. He had suddenly become completely hemiplegic upon the left side; was unconscious and had stertorous respiration; he passed his urine and feces in bed. Recovery gradually took place from the unconscious state, paralysis remained on the left side. Trophic troubles began in the joints of the paralyzed arm, accompanied with pain. Patient would cry when spoken to, and could give no history of himself. At this attack Dr. Shaw concluded that there was cerebral arteritis, probably syphilitic, and thrombosis. The patient accused his wife of infidelity, became very noisy at night, and was sent to an institution, where he died in October, 1884.

At the autopsy the viscera appeared to the naked eye to be normal. Nothing special was observed in the meninges. The ventricles were distended with fluid, and contained granulations. The corpora striata were softened, due to arteritis of both middle cerebral arteries and their branches. There was secondary degeneration in the cord on both sides, and the case seemed to illustrate the unequalness of the decussating fibres on the two sides, the degeneration on the right side in this instance being much more marked than on the left.

Dr. Shaw said the points of interest to him were, that both arteries should have been involved in the arteritis, causing softening of the corpora striata on both sides. That the patient saw dogs, etc., at night, which might have been a form of visual hallucination. Lastly, the accusation of his wife of unfaithfulness, a symptom which is frequently met in chronic alcoholics, but rarely in other conditions.

DR. E. C. SEGUIN asked if there was not probably involvement of at least one internal capsule.

DR. SHAW replied that there was, and that the case probably was not one of limited involvement of the corpora striata.

DR. SEGUIN thought a point of interest was the fact that granulations were found in the ventricles, for this is a rare pathological condition except in general paralysis. It is sometimes found in other conditions, as chronic mania.

DR. SHAW said that the granulations in this case were marked. He had seen granulation on the floor of the ventricles in a variety of conditions in the chronic insane and others. Sections of the cerebral cortex did not show the lesions characteristic of general paralysis. Dr. Seguin may have noticed that the patient was unusually satisfied with his condition, almost amounting to a delirium of satisfaction.

DR. GRACE PECKHAM then read a paper entitled

MIRROR WRITING AND OTHER PATHOLOGICAL CHIROGRAPHY OF NERVOUS ORIGIN.

The paper was introduced by a reference to the expression of individuality in handwriting. "As the members of the body are the servants of the brain and carry out its will in motion, as the vocal organs express its thoughts in sounds, so in the act of writing the hand embodies the subtleties of cerebral action; it is therefore in writing that we may find expressed deviations from normal nervous conditions, sometimes too slight to be indicated in any other way."

The physiology of the handwriting was next considered. Poore's views with regard to the muscles employed in the act of writing were quoted. At no time in the act of writing are fewer than two nerves engaged. The cerebral centres which preside over writing and the inter-commissural tracts are not fully made out. Charcot and others think there is a word motor representative centre situated at the base of the left third frontal convolution near Broca's centre of speech; auditory centres, employed when writing to dictation, in the temporal convolution; ocular centres, used when copying, in the parietal convolution.

We have a right-handed writing to be written with a centrifugal motion, in one direction, across the page from left to right, a writing which taxes the weak muscles of the hands, and which takes four or five times as long as is necessary for the representation of a word, as is shown by stenographers, who write as fast as a person can speak. In view of the increase of writer's cramp due to the extraordinary amount of writing to be done by bookkeepers, book-writers, teachers, and savants, it was suggested that a new method of writing should be intelligently discussed and one inaugurated which should be less elaborate, less taxing upon the small and weak muscles of the hand; a handwriting in which the letters can be formed as in phonography, disconnected, not requiring such precise and complicated notions to make them legible, and which can be written from above downward, from right to left or left to right, as one may choose.

Bianchi, in Italy, and Erlenmeyer, in Germany, were almost the only ones who entered into the study of the pathological signification of the handwriting. The subject has been considered in a disconnected way as a symptom of some diseases treated of in various textbooks. However remotely alluded to, there has been a general acknowledgement of the diagnostic value of the handwriting of disease.

The handwriting may become pathological through the alteration of any portion of the mechanism involved in its production. The paper included only a discussion of the changes produced by abnormal conditions of the nervous apparatus. Alterations in the handwriting may be mechanical or psychical, ataxic or tremulous, or a mingling of the two forms. The ataxic form is physiological when seen in childhood, before the power of coördination of muscles for the complex act has been acquired. The tremulous form is physiological in the handwriting of the aged, in which also is seen a tendency to retrograde into childish handwriting. The principal pathological handwritings are:

1. Handwriting resulting from trauma to the nerves. 2. Mirror writing and agraphia, caused by injury to the cerebral centres. 3. Handwriting of general paralysis, caused by alteration of cerebral tissue. 4. Handwriting as influenced by sclerosis, cerebral and spinal. 5. Handwriting as influenced by functional disturbance, including paralysis agitans and writers' cramp.

Samples of handwriting can be shown occasioned by the interference with the conducting nerve-fibres. Erlenmeyer exhibits a very curious specimen in which there was injury to the radial nerve. The tremulousness, or, rather, interruption of the lines, especially of the upper stroke, is very peculiar.

It is to be regretted that handwriting following injury to nerves has not been more studied, as much of interest from a physiological as well as a pathological point of view might be attained.

At present, considerable discussion has been awakened with reference to mirror writing. Ireland called especial attention to it by his paper on the "Brain," in 1883. Hughlings-Jackson and Buchwald first discovered mirror writing. From experimentation and investigation of the subject, the writer reached the following conclusions:

First, that mirror writing may indicate a change in the perception of the nerve-centres of the brain, what Erlenmeyer would call retrographia. The patient suffering from this would read the reversed writing certainly as easily as the normal. This would be a means of diagnosis between a cerebral mirror writing and one from mechanical causes alone. Second, that from careful examination of twenty-five cases on record, no indication has been found that the mirror writing occurred from other cause than a mechanical one—that is, the person writing with the left hand could do so more easily in a centrifugal than in a centripetal direction, the former association of ideas and muscular action making this so. Therefore, persons weakened by disease, or weak-minded children, in using the left hand, would write centrifugally—that is, produce mirror writing. The reason lies, therefore, not in a pathological but in a physiological condition.

The subject of agraphia has been much discussed of late with that of aphasia. It was first spoken of by Marce, in 1856. There are on record very few cases of agraphia uncomplicated with aphasia. In agraphia there may be word-blindness, word-deafness, or a volitional motor disturbance, resulting in inability to write

The investigators of the subject have entered deeply into the discussion of the seat of the writing-centre in the left hemisphere. The unilateral theory is not so fully endorsed as hitherto. The diagnostic value of the handwriting in agraphia resides in the evidence it gives of the extent of damage done to the brain tissue in these cases of hemiplegia, and also an indication of the location of the trouble.

In the early stages, the handwriting of the insane indicates little the invasion of the disease; but when there are bad spelling and omission of words, it should awaken suspicion. The progress of the malady is marked by changes in the handwriting. It is the reverse of that of childhood. In the first stage there is a diminution of the handwriting, a running of the words together, and either not finishing the final letter, or terminating it in an irregular outline, or dropping it entirely. The letters are shaky, irregular, and there is a plentiful besprinkling of capitals. Later the letters are coarse, irregular, in uneven lines, and finally there are scattered pot-hooks and ataxic marks, like those of a child first learning to write.

The handwriting of multiple cerebro-spinal sclerosis is chacterized by tremulousness.

In locomotor ataxia involving the upper extremities, the changes are shown early when writing with the eyes closed, especially in round letters, and *l* and *e*. They are formed by straight lines more or less extended, instead of curves. When the disease is further advanced, the writing is ataxic when the eyes are open, though not so much so as when they are closed. Later there is inability to write a single word.

The functional disturbances of the handwriting include the writing of paralysis agitans and writer's cramp, as also that of chorea and hysteria. In the two latter there is nothing of special diagnostic value. The writing of paralysis agitans shows the tremor in the early stages. Even when the handwriting looks normal to the naked eye, a glass will reveal the peculiar character given it by trembling. In writer's cramp the writing shows many forms of disturbance, and were there no history, it would be difficult to say whether we were dealing with some of the various forms of tremor, paralysis agitans, progressive muscular atrophy, etc. A study of the handwriting will, however, reveal the nature of the disturbance, whether it is of the spastic, treumulous, or paralytic form.

Dr. E. C. Seguin said that in his practice he has frequently derived considerable help in diagnosis from the patient's handwriting. He thought the medico-legal aspect of pathological handwriting might, after further study, assume considerable importance. It would be of value to be able to say in a court of law whether a given specimen of handwriting was that of an aged imbecile, a general paralytic, or an intoxicated person.

Dr. Leszynsky thought we could hardly say from the specimens of handwriting of paralysis agitans presented that they were characteristic of that disease. He had a number of specimens of handwriting of chronic alcoholism, which were almost exactly similar. Dr. Peckham had not mentioned the handwriting of epileptics, nor had he read of anything characteristic about it, but he could recall two epileptics whose handwriting appeared to be rather unique. In some epileptics there is the condition known as the echo sign, being a repetition of words during conversation. He had seen the same thing manifested in the writing in two cases. He has recently had a case of telegrapher's cramp, in which the hand movements were markedly ataxic, being without any control.

Dr. M. Putnam Jacobi has been struck by the great varieties and peculiarities in the handwriting of persons in usual health; some of the peculiarities supposed to be more or less characteristic of the handwriting of diseased states were also observable in the handwriting of certain persons in a state of health. For instance, Dr. Jacobi is unable, without giving special attention, to write in a direct line across the page; the line always sloped downward. The question has suggested itself to her whether, in the case of the insane, the tendency, especially after writing for a while, to slope the lines downward and to use capitals profusely, is not due to mental fatigue; and the use of capitals may be due to a desire to emphasize an idea which a fatigued and feeble brain is incapable of correctly expressing.

Dr. Dana said he did not think it would be practical for everybody to learn short-hand instead of other writing, but he thought some modification of short-hand might be adopted. There would result perhaps greater facility of expression if present methods of writing were simplified, but there would no doubt be an increased amount of writing, which, perhaps, would be a greater misfortune.

Regarding mirror writing, he thought it is physiological. When we educate the centres to write with the right hand, we at the same time educate to some extent the automatic centres for left hand or mirror writing. If a person put a pencil in either hand and attempt to write his own name, he will find that the left hand will write mirror writing, while from the right hand the usual writing will result. If then by hemorrhage the centre for right handwriting be destroyed, it is perfectly natural for the centre controlling left handwriting, if not corrected by the will, to produce mirror writing.

Dr. A. B. Judson presented a specimen of mirror writing by a negro girl, eleven years of age, produced ten years ago. She had slight right hemiplegia, but was able to perform household work with the right hand, and she could also write somewhat with it. The writing with the left hand was a fine specimen of mirror writing.

Dr. Peckham closed the discussion, and said that the echo sign, the repetition of written words, was well shown in the third specimen presented, that of a woman who had right hemiplegia and amnesic agraphia. Regarding the use of capitals and the tendency to underscore by the insane, she thought they were in harmony with their exaggerated ideas.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, January 5, 1886.

The President, T. G. Roddick, M.D., in the Chair.

RAPIDLY GROWING OVARIAN TUMOR.

Dr. Trenholme showed a large semi-solid ovarian tumor which he had removed from a woman some days before. The patient, when she consulted him, was unaware that she had a tumor, but consulted him for severe abdominal pain, which had lasted some three weeks. She had only noticed a swelling for the last six weeks.

Latterly, the tumor had grown very rapidly. It was removed without great difficulty, though the adhesions were numerous and the operation was complicated and prolonged by the bursting of a cyst. The pedicle was broad, and, as is his custom, he ligated it in sections with shoemakers' thread. The patient's temperature rose to 101° the day after operation, but soon fell to normal, and remained there.

DR. SHEPHERD mentioned that a short time ago he had operated in a case of ovarian tumor (in a childless married woman aged twenty-nine), with a history of only eight weeks' growth. The patient was seen by Dr. R. P. Howard a month before the operation, and at that time the tumor was of small size; it grew very rapidly, and in three weeks was quite large. At the time of operation, it was doubtful whether this rapid increase was not due to ascites. However, it proved to be a single ovarian cyst, with a solid base, containing twenty pints of thick fluid, and weighing some five pounds. The patient did well, and was able to return to her home in four weeks.

UNDEVELOPED BONES IN AN IDIOT.

DR. R. L. MACDONNELL showed the bones of the lower extremity of an idiot, which had been sent to the dissecting-room of McGill University from one of the institutions of the city. The individual was said to be twenty years of age, and had never spoken or walked. The bones, although of good length, were remarkably small, the femur not being thicker than an ordinary sized finger. The hip-joints were ankylosed in the flexed position, and there was contraction of the knees. The muscles of the lower extremities were strings of fibrous tissue with a little muscular tissue about them. The head, although somewhat microcephalic, was of good shape. In one femur there was a well-developed third trochanter.

HEMORRHAGE INTO THE PONS VAROLII.

DR. R. L. MACDONELL read the history of a case of hemorrhage into the pons Varolii. An old man, æt. sixty-two, was admitted into the Montreal General Hospital on July 31, 1885. He had been picked up by the police in the streets, and was in a semi-unconscious condition, unable to communicate anything whatever regarding his history. He was a tall, thin man, very anæmic, with wasted and flabby muscles. His expression was dull and listless, and, though he could utter words when spoken to, he was by no means rational. The pupils were equal, but the left was more sluggish than the right. There was slight paresis of the left side of the face, and the right side of the body was weaker than the left. There was increase of the superficial reflexes, but normal patellar reflex. The urine and feces passed in bed; he was always in a semi-comatose condition; pulse 90, and feeble. On the 3d of August, his breathing was stertorous, and the paresis of the left side of the face more marked, and coma more profound. Next day, the coma was complete, pupils contracted and unequal; large, moist râles heard at the bases of both lungs; toward evening, he died comatose.

The brain alone was examined after death, when a fresh clot was found in the pons Varolii, occupying the posterior or lower part, and situated rather more to the left than the right side. Dr. MacDonnell remarked that the central situation of the clot was shown by the equality of the paralysis on either side, and the greater weakness of the right side being accounted for by the position of the clot. It was a case of alternate hemiplegia, the left side of the face being paralyzed, though to a slight degree. This is characteristic of positive hemiplegia, especially when the lower half of the pons is injured, though usually the fifth and sixth nerves are also involved. There was nothing distinctive in the condition of the pupils, which were not, as usually described, contracted, but merely sluggish in their reaction to light. In hemorrhage into the pons, one of two opposite conditions is usually observed: contraction of the pupils when the lesion is sudden and situated in the upper part of the pons, causing irritation of the nuclei of the third nerve; and dilatation from complete invasion and destruction of these nuclei.

DR. HENRY HOWARD asked if, at the post-mortem, the ruptured vessel had been found, as it was most important to know exactly the source of the hemorrhage.

DR. WILKINS related a case of very extensive hemorrhage into the pons, when the patient lived for eight days.

DR. STEWART asked if the whole of the left facial was affected or only the respiratory branches?

DR. MACDONNELL, in reply, stated that the ruptured vessel had not been found, and that the whole of the facial was paretic.

CEREBRAL SYPHILIS.

DR. GEORGE ROSS reported a case of supposed cerebral syphilis which had occurred in his wards in the General Hospital since his paper on that subject was read before the Society. The patient died a few days after admission, and a post-mortem was obtained. He came into hospital complaining of very severe pain in the head and vomiting. In a day or two he was quite maniacal, and then gradually became comatose. He died comatose five days after admission. At the post-mortem, Dr. Wyatt Johnson found at the base of the brain a single small flake of recent lymph, lying on and attached to the inferior surface of the facial nerve in the right side, near its origin. On slitting up the vessels at the base, this exudation was seen to correspond to a small lateral branch of the basilar artery, where it crossed the nerve. The thrombus extended in this vessel as far as its origin from the basilar, at which point a small roughened, reddish patch existed in the intima, and its wall was thickened, but no thrombus present. The right posterior cerebral artery presented a thickened wall and narrow lumen, and was thrombosed in its whole course; other cerebral vessels normal. On dissecting the brain, no local degenerative changes were recognized anywhere. Dr. Ross remarked that it was singular that such apparently simple lesions should produce such grave symptoms. He had expected to find much more marked pathological changes in the brain.

TREATMENT OF ERYSIPELAS IN INFANTS BY ZINC PAINT.

DR. A. D. BLACKADER read a short paper on the local treatment of infantile erysipelas. After giving an account of the treatment by white lead paint, which he had used to some extent, he said that it had occurred to him to use zinc paint instead in infants less than a year old, so as to avoid any risk of lead poisoning. He used

zinc white made into a paint with linseed oil, and found it a very soothing and cleanly application. He brought forward this method of treating erysipelas as being more easy of application, and more rapid in its results than the old treatment by lead lotion, cotton-wool, corn starch, etc. No bandages were applied to get disarranged or soiled. Whenever the parts are exposed, all the mother has to do is to apply the paint. In this way the application is more continuous, and the results are in consequence better. At the same time that he used local treatment he employed also constitutional treatment by iron and stimulants. He believed that erysipelas is a constitutional disease, and needs constitutional as well as local treatment. He reported a number of cases in very young infants, where the pain and irritation were immediately allayed by the application of the paint, and where the temperature soon fell.

POSTERIOR CERVICAL LACERATION OF OS UTERI.

DR. T. JOHNSON ALLOWAY reported a case, illustrated by diagrams, of severe posterior cervical laceration. The patient had suffered for years from violent hysterical attacks, and was never free from pain—in fact, she was a confirmed invalid. The parts were pared and brought together, with a most satisfactory result. The woman is now as well as ever, and able to attend to all her household duties. Dr. Alloway remarked that severe posterior laceration is a very rare affection; the slighter forms are not uncommon, and unite without operative interference.

SALIVARY CALCULUS.

DR. HINGSTON exhibited a large salivary calculus, which he had removed a few days ago from a lady who had been sent to him for supposed cancer of the tongue. There was great inflammatory swelling of the under part of the tongue.

BALTIMORE ACADEMY OF MEDICINE.

Stated Meeting, January 6, 1886.

DR. J. J. CHISOLM presented the following notes on

A PIECE OF IRIS LIVING IN THE VITREOUS CHAMBER.

G. T. S., aged fifty-nine, six months ago fell down a railroad embankment, receiving an injury to the right eye. When seen by his family physician six hours after the accident, he was suffering intensely. The lids had already become very much swollen. Upon carefully separating them, a wound was discovered at the upper edge of the cornea, from which a thick splinter of wood was protruding. The removal of this bit of wood was accompanied by a bloody aqueous discharge, leaving, however, so much blood in the anterior chamber as to conceal the amount of injury done to the eye contents.

The treatment pursued was rest, cold applications, and the internal administration of anodynes. As the swelling subsided and the blood was absorbed, it was found that sight had been so materially impaired as to leave only perception of light. In time, however, the vision slowly improved, till after three months large objects could be again recognized. In the mean time, the left good eye indicated some growing impairment of vision for distant objects, and the spectacles heretofore worn with comfort no longer permitted easy reading.

This growing defect of vision in the good eye was supposed to be a sign of sympathetic complications, and for this reason the patient was sent to me for surgical treatment.

I found the left good eye hyperopic, V. $\frac{15}{40}$; with a $+\frac{1}{20}$, his distant vision became $\frac{15}{15}$, even above normal, and he read brilliant type readily with a $-\frac{1}{8}$ lens. His spectacles were $-\frac{1}{12}$, which accounted for his discomfort. At first sight the injured right eye presented every appearance of a successful cataract extirpation.

The iridectomy was large, well shaped, centrally located, and clean to the very ciliary border. The well-formed artificial pupil was black, with traces of capsular deposit as is seen after successful cataract operations. He could detect large objects and count fingers readily at four feet, the distance at which I was sitting from him.

In putting a $+\frac{1}{8}$ lens before his injured eye I was surprised to find V. $\frac{15}{70}$, and with a $+\frac{1}{2}$ of $\frac{1}{8}$ lens he could make out words in brilliant type.

He complained of something moving about in his eye, which seemed to wave before his sight. By oblique illumination I could see a whitsh body in the vitreous. With ophthalmoscopic illumination the examination showed a healthy fundus and clear vitreous, so as to give a perfect retinal picture.

Hanging from the roof of the vitreous chamber at some little distance behind the thin, partial capsular film, was a flap of membrane apparently one line wide and two lines in length. It was rectangular in shape and of a yellowish-white color. Upon its anterior surface could be clearly traced a vessel of some size, which, starting at the base, ran down through the whole length of the membrane, to the free extremity of the flap.

This piece of living tissue moving to and fro in the vitreous with the movements of the eyeball, and adhering to the upper anterior edge of the choroid, could be nothing else than the missing piece of iris.

The splinter of wood in entering the eye through the upper scleral border of the cornea, had torn the iris in two places from the pupillary border to the ciliary region, in this way punching a piece out of it. This detached bit of iris had been pushed back into the vitreous chamber, carrying with it a portion of its ciliary body. It remained adherent to the ciliary body at one point by a broad base.

The lens must have been injured also at the time of the accident, because through its torn capsule the aqueous humor had been brought in contact with it, resulting in its complete disappearance by absorption.

As there was a broad base to the flap, with ample nourishing bloodvessels, the piece of displaced iris had continued to live. Under ophthalmoscopic examination it showed boldly as a whitish-yellow membrane against the healthy red reflex of the fundus. Curiously, the passage made by the splinter into the vitreous chamber had not been invaded by inflammatory deposits. The hyaline structures had taken on no pathological changes, and, therefore, excellent vision had been retained in this curiously injured eye.

DR. J. EDWIN MICHAEL then related

AN UNUSUAL CASE OF GUNSHOT WOUND.

On Christmas night last, about nine o'clock, he was called to see a large, stout, well-built German man, a

saloon-keeper by occupation, who had received a pistol wound, while engaged in quelling a disturbance in his establishment.

The ball came from a pistol of the "Bull Dog" pattern, 38 calibre, and was shot from a distance of twelve to fourteen feet in front and a little to the right of the patient.

Upon examining the patient it was seen that the point of entrance of the ball was at a spot almost if not directly over the apex of the heart.

Later measurements showed the exact location of the perforation to be three inches to the left of the median line, an inch and a half to the right of left nipple line, and three-quarters of an inch below a line drawn transversely through the nipple. There was, of course, no probing. The patient was in a condition of extreme shock; stimulants were given, and after a short time consciousness returned. Upon examination by physical signs, a wound of the lower lobe of the left lung and hemorrhage into the pleural cavity of that side was diagnosticated. It was also probable that there was a coexisting pneumothorax of small degree. About eleven o'clock, two hours after the accident, the patient began to complain of much general pain. He became quiet after a hypodermatic of morphia and atropia, and continued comparatively easy for a time, when pain again began to be felt, which was arrested by a repetition of the hypodermatic injection.

At the end of twenty hours from the time of the accident, the patient died.

The autopsy showed that the bullet had passed through the fifth rib, near its junction with the cartilage, through the pericardium, through the left ventricle, making an opening at its point of entrance and another at its point of exit, which two openings were connected by a furrow in the ventricular wall, ploughed up by the ball in its passage through the heart. After leaving the heart, it had penetrated and passed through the lower lobe of the left lung, fractured the eleventh rib, and embedded itself in the soft tissues of the back, about two inches to the left of the spinal column.

He thought it remarkable that such a ball should have passed through the heart without causing instant death. He had seen one other case in which the heart had been perforated by a 22 calibre ball. In this case death was practically instantaneous.

In the case under consideration the wound was obliquely through the heart in such a way as to make valve-like openings in the ventricular walls, similar to the openings in the bladder through which the ureters pass. This form of perforation, he thought, prevented what would have been rapid hemorrhage into the pericardium, had the openings been made in a line perpendicular to the plane at the point of entrance of the ball.

During life there was considerable hemorrhage, but he did not think that it came directly from the heart, but was forced from the pleural cavity by the movements of the lung in respiration. The dressing consisted of cloths saturated in bichloride solution.

DR. J. J. CHISOLM said that, of course, we had all heard of the rare case of perforation of the heart and retention of the bullet within its cavity until found there after death. He had seen cases of injury to the heart by bullets, but none of them had lived so long as twenty hours.

DR. A. B. ARNOLD next read a most exhaustive paper on

CIRCUMCISION,

in which he treated the subject from a moral as well as from a historical and surgical standpoint.

He protested against the practice, not only because he considers it detrimental in robbing the glans of its natural protective covering, and thus exposing to irritation the very sensitive Pacinian bodies about the corona, but because the result of this exposure and consequent irritation, he thought, led to habits of masturbation.

In answer to the question, "Had any hereditary shortening of the prepuce been observed in Hebrew children as a class?" he said he had noticed nothing different in the formation of the foreskin in them from that of other children.

DR. J. EDWIN MICHAEL thanked Dr. Arnold for his paper. He had some time since read an article on the subject from a surgical standpoint. In his experience he has frequently been called upon to remove the prepuce because of its inconvenience. As to affecting the sensitiveness and irritability of the glans, he did not see that the operation made any difference whatever, for how very often do we see men with naturally exposed glans from an abnormally short prepuce. They present no greater degree of sensitiveness. He thought with some eminent authorities, that the sensitiveness of the glans is increased by circumcision of a long prepuce and the irritability decreased.

NEWS ITEMS.

HYGIENE IN JAPAN.—A Bureau of Public Health, on the plan of those existing in Germany, has just been instituted in Tokio. The Director is Prof. Ogata, who has studied for several years in Munich, Leipzig, and Berlin, especially in the laboratories of Pettenkofer and Koch.

AMERICAN AND BRITISH LAUDANUM.—The *Pharmacist* remarks that the tincture of opium of the new British Pharmacopœia is directed to contain about 0.75 per cent. of morphine, while the United States preparation contains about 1.4 per cent., if opium of mean standard strength is employed; and that, therefore, the difference in strength between the two laudanums is almost 100 per cent.—*N. Y. Medical Journal*, January 2, 1886.

NEW YORK PHYSICIANS SEEKING PROTECTION.—Drs. E. G. Janeway, A. Jacobi, Austin Flint, and twenty other physicians, have sent to the Board of Health a written protest against the liability to suits for damages which physicians are made to assume when in good faith they report supposed cases of contagious diseases. A recent suit against a physician, who reported that a woman had smallpox when she was suffering from another disease, was the cause of the protest. It was said that physicians might neglect to report dangerous cases of typhus fever or smallpox if something was not done to change the law. The Board was urged to prepare a bill for the Legislature to exempt physicians from the legal consequences of too hasty reports in cases of suspected contagion. No action was taken on the communication.

Alcohol and Disease.—Dr. Dawson Burns, the Honorary Secretary of the London Temperance Hospital, referring to the statement made to the Local Board of Winsford by the District Medical Officer that, in his opinion, three men who lately died from what seemed an attack of cholera, owed their deaths to the refusal to take alcoholic liquor, calls attention to the fact that the alcoholic treatment of cholera has confessedly proved a failure, and that recoveries have been far more numerous where it has been dispensed with. It is an admitted fact that the ordinary use of alcoholic drink, instead of being a preventive of that disease, rather predisposes to it. The superstitious value attached to alcohol in the treatment of disease is fast disappearing from enlightened medical circles; that the use of alcoholics in the great London hospitals is largely diminishing, with good results; and that the experience of the London Temperance Hospital, where alcohol has been given in only three out of three thousand in-patient cases, with an average annual mortality of five per cent. during twelve years, is exposing the fallacy under which the medical officer of Winsford appears still to suffer. —*British Med. Journ.*, Jan. 2, 1886.

Cremation in Paris.—Much further interest, we learn from the *British Medical Journal* for Jan. 2, 1886, continues to be excited in Paris by the recent decision of the Municipality to erect a crematorium at Pére la Chaise, for which plans have been accepted. It is settled that the expense of cremation is not to exceed fifteen francs, and the time required for combustion will be two hours. It is in contemplation to erect a suitable building for the reception of urns or other funereal vessels containing the ashes of dead relatives, and the artistic world is already discussing the æsthetic side of cremation, while M. Koecklin Schwartz points out that persons of all denominations may unite in erecting a vast mausoleum, in which the ashes of thousands could be deposited in beautiful vessels without injury to the living. This is, however, looking rather far into the future.

The Treatment of Epilepsy.—The prize of 8000 francs offered by the Belgian Academy of Medicine for an elucidation by clinical facts of the pathogenesis and treatment of diseases of the nervous centres, and principally of epilepsy, has not been awarded; but a sum of 500 francs is offered by way of encouragement to the author of the essay bearing the motto, "Traditionem pondero, doctrinam respicio, sequor veritatem," on condition that he allow his essay to be printed in an abridged form with the criticisms of the Commission.—*Lancet*, January 2, 1886.

Absence of Hydrophobia in Berlin.—M. Paul Gibier, who has continued his studies of hydrophobia in the laboratory of Koch, writes to the French Academy of Medicine that he has been absolutely unable to obtain a rabid dog in Berlin, and that the physicians in the Imperial Veterinary School in that city state that they have not seen a rabid dog for more than three years.

M. Gibier attributes this condition of affairs to the fact that *in Berlin all dogs are muzzled.*

A Physiologist's Will.—On the first page of the will of the late Prof. Robin is the following request to the heirs:

"If I die in Paris, let my autopsy be made at the earliest possible moment after my death, by one of the prosectors or assistants of the École de Médecine, to be designated by the Dean. My brain and eyes should be removed and studied comparatively. The left eye was destroyed by a blow in 1835, and the optic nerves and convolutions should be studied with this fact in view."

Presidency of the French Academy of Medicine.—M. Sappey, Professor of Anatomy in the Paris Faculty, has just been elected President of the Académie de Médecine.

Dr. Augustin M. Fernandez, late editor of *El Repertorio Médico* of New York, has removed to New Orleans. He has recently been elected Corresponding Member of the Academy of Medicine of Madrid, Spain, and of *El Circulo Médico Argentino* of Buenos Ayres, Argentine Republic.

Juvenile Intemperance in London.—The Bishop of London, in addressing the metropolitan members of the United Kingdom Band of Hope, congratulated himself and his fellow-teetotallers on the number of children growing up in London on temperance principles. This is a good fact, upon which society is, indeed, to be congratulated. There are few subjects on which mediual authorities are more agreed than in thinking that children are far better without any form of alcoholic stimulant, and juvenile education of this sort is the best counteractive of that deeply inherited vice of English children, which is the result of what Dr. Valpy French calls, in his interesting book, "Nineteen Centuries of Drink in England." Recent Christmas days have given painful evidence that all London boys, or girls either, are not of the Band of Hope. It is a pitiable sight to see boys and girls of sixteen or eighteen reeling along the streets. All honor to the Bishop and his coworkers, who, we trust, will be supported by hosts and hostesses in the remaining holidays. The beverage at all children's entertainments should be non-alcoholic.—*Lancet*, Jan. 9, 1886.

A death from chloroform has occurred at Tunstall, England. The anæsthetic had been administered twice to the deceased on previous occasions, and he had come well out of it, but the third time proved fatal.

A New Chair.—Dr. Lenoir has been appointed to the newly created chair of Cutaneous and Syphilitic Diseases, at Lille.

Official List of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Two Weeks Ending January 16, 1886.

Sawtelle, H. W., *Surgeon*.—To proceed to Los Angelos and Wilmington, California, as inspector, January, 1886.

Godfrey, John, *Surgeon*.—To proceed to Chattanooga, Tenn., and Rome, Ga., as inspector, January 8, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLVIII. SATURDAY, JANUARY 30, 1886. No. 5.

ORIGINAL LECTURES.

ON ANTISEPTIC PULMONARY MEDICATION.[1]

A Clinical Lecture, delivered in Cochin Hospital.

BY PROFESSOR DUJARDIN-BEAUMETZ,
OF PARIS, FRANCE.

GENTLEMEN: One may affirm, without fear of being accused of exaggeration, that antiseptic pulmonary medication, such as we may ideally imagine it to be, is destined to have a high place in the therapeutics of the future. In fact, in all that concerns the contagion of diseases, the air is the most important factor, and whoever shall succeed in depriving the atmosphere of its germs, will render the greatest possible service to medicine and to hygiene.

Thanks to the brilliant discoveries of Pasteur, and to Miquel's patient investigations, we know to-day by scientific means, not only the number of the microorganisms which flit about in the air, but also the divers varieties of these microbes, which belong especially to the genera micrococcus, bacillus, and bacterium, but more particularly to the first of these genera.

Microbiologists have even gone further; they have commenced the study of these different schizophytes from a botanical point of view, as well as from a physiological; and there is one fact which we have learned from these studies, namely, that when the bacteria thus collected from the air have been cultivated in suitable media and inoculated in animals, they have given rise to nothing but negative results, and it has not yet been possible to reproduce in animals contagious diseases by the introduction of these microörganisms. But, as Miquel has justly remarked, these results should be accepted with the greatest reservation, and one may well ask if the procedures put in usage for the collection and cultivation of the schizophytes may not be sufficient to destroy their virulent properties.

As you might have foreseen, the greater part of these microörganisms—that is to say, eighty per cent.—are aërobiotic—*i. e.*, they have need of oxygen to live and develop.

As for their number, I showed you in one of my late lectures that this varies according to the localities where they are collected, and that the purity of the air is in inverse proportion to the microbes it contains. While in high altitudes you find but very few microbes to each cubic metre of air, it is by the thousands that you meet with them in our hospital wards; and when you reflect that a man breathes through his lungs in twenty-four hours ten cubic metres of air, you can form an estimate of the prodigious number of microorganisms which penetrate by this channel, which forms the most easy and rapid mode of entrance into the organism of infectious or medicinal principles. In fact, substances which penetrate by the lungs, are carried almost directly to the left ventricle, and thence are distributed through the entire organism, and this explains the interest which Claude Bernard took in the method of tracheal medicinal injections in cases of urgency.

I am well aware that, by a lucky anatomical conformation, man breathes only exceptionally by the mouth, and that the air penetrates chiefly by the nasal fossæ, which, by their anfractuosities, act the part of the filtering apparatus employed by Pasteur to purify the air, but this filtration is very often incomplete, since it is by the pulmonary passages that the contagious and infectious diseases are chiefly transmitted.

I cannot here, in this purely medical lecture, discuss in its entirety the subject of antiseptic pulmonary medication, which, by its developments, constitutes one of the grandest chapters of modern hygiene, that of the aëration, ventilation, and disinfection of dwelling-houses.

I shall only refer in this connection to the divers experiments in which you took part on the occasion of the recent cholera epidemic, when Dr. Roux and myself, under the direction of M. Pasteur, showed that of all the antiseptic gases, the most active is sulphurous acid, and this chiefly by reason of its power of penetration. We proved that in the proportion of twenty grammes to each cubic metre of space, sulphur in undergoing combustion destroys the microörganisms contained in a liquid, and that in the proportion of forty grammes to each cubic metre it destroys the same microörganisms in a state of desiccation. But in such media man cannot live, and what we want especially to find, is some safe disinfectant, whether liquid or gaseous, which will destroy the schizophytes, while permitting man to sojourn in the medium where this disinfection is practised.

I know that researches in this direction are being earnestly pursued, and that hope has been entertained that we may find in ozone one of these parasiticide agents, but thus far experiments have not given results confirmed with all the scientific rigor which such researches demand. Others, going back to a notion already put in practice in the middle ages, have thought that the introduction of these microörganisms into the economy might be avoided by the application of protective masks or respirators, such as are used in workshops and factories where the air becomes impregnated with noxious dust; the breathing air being filtered through layers of cotton. I will not dwell longer on this point, desiring merely to hint at this side of antiseptic pulmonary medication. But there is another aspect of the question on which I desire to dwell longer, it is that which concerns the destruction of certain microörganisms which are the efficient causes of pulmonary affections, and I wish in particular to say something about the action of antiseptic substances on the microbe of tuberculosis.

[1] Translated, from advance sheets, by E. P. Hurd, M.D., of Newburyport, Mass.

When at the end of 1882 Koch, in his remarkable communication, demonstrated the microbiotic nature of phthisis, he by this discovery revolutionized the history of tuberculosis, and gave a striking experimental confirmation of the theory advocated many years before by my learned colleague and friend Dr. Villemin.

When Villemin in 1865, in his brilliant work on tuberculosis, announced that this disease was virulent, contagious, and inoculable, he raised in the medical world a real tempest, which was not allayed at the time of the appearance of Koch's researches, and many of the most eminent physicians disputed several of the terms of Villemin's definition. To-day all disputation has ceased before experimentation, and everybody is agreed that the bacillus tuberculosis is the real contagious agent of this disease.

But the application of Pasteur's views was destined not to be limited to tuberculosis; these views were soon to modify and revolutionize a disease which has been considered as the type of inflammatory diseases. On the 19th of November, 1883, Friedlander, completing the first researches which he had made in 1882, showed by decisive experiments that there exists a schizophyte proper to pneumonia, and a few days later, namely, November 30th, Talamon, at the Anatomical Society, made known the result of his researches, and showed that if he did not absolutely agree with Friedlander respecting the form of the bacillus observed, he none the less considered it as the causal agent in pneumonia.

These experimenters thus gave justification to the tentatives made in 1878 by Klebs, who, under the name of *monas pulmonale*, had described a microbe peculiar to pneumonia.

This discovery of a microörganism as cause of certain pulmonary affections ought to be utilized by therapeutics, and just as in basing myself on new experimental researches, I endeavored to establish an antiseptic intestinal medication, so also I would venture to suggest the first principles of an antimicrobic pulmonary medication:

Let us see first what data experimentation can furnish us, and here I shall take as my basis the labors recently undertaken in France, and, in particu' , the able researches of Hippolyte Martin, who .s performed experiments of the greatest interest on tubercle and inoculation by tubercle.

Hippolyte Martin first established the fact that inoculation constitutes the best means of recognizing the real nature of tubercle. When, in fact, you inoculate in animals—guinea-pigs or hares—foreign bodies, or septic matters, you determine in these animals granulations more or less generalized in all the viscera, and which macroscopically and microscopically are identical with tubercles. But that which enables us to distinguish pseudo-tubercles from true tubercles, is that the former have no power to produce tuberculosis in other animals, while, on the contrary, true tubercle indefinitely reproduces the same disease in animals in which it is inoculated, so that even before the discovery of Koch's bacillus (as early as 1881), Hippolyte Martin had been able experimentally to demonstrate the proposition: *tubercle alone engenders tubercle.*

From these experiments, this capital fact is put in clear light, that when you would judge of the real value of antiseptic substances in the destruction of the bacillus of tuberculosis, it is not sufficient to practise one inoculation alone, which may cause the production of pseudo-tuberculous granulations, but the inoculations should be in series—*i. e.*, the products of one inoculation being inoculated in another animal, and so on, and all experimenters who have not taken care to avoid this source of error, must expect to see their results called in question.

Repeating the experiments of Arloing, of Cornevin, and of Thomas, who had made trials of the different antiseptic agents to antagonize the anthracoid bacteria, Hippolyte Martin, in his turn, experimented with these antiseptics against the bacillus tuberculosis. This was his manner of procedure: He crushed and pressed portions of viscera studded with tubercles, and the juice which he squeezed out was put in contact with the fresh amniotic liquor of a sheep, and to the whole was added a given quantity of the medicament to be experimented with; in this way trials were made with salicylic acid, bromine, carbolic acid, creasote, quinine, and corrosive sublimate. These mixtures were injected into the peritoneum of guinea-pigs, and on the death of the animals the inoculations were continued in order to ascertain the real value of the granulations which were found at the autopsy.

In the case of salicylic acid, solutions of five per cent. were powerless to destroy tubercle. Bromine in solution, 1 per 10,000, and 1 per 1000, also proved to be inefficacious; at 1:500 the action was more marked, but in this strength the solutions are caustic. In the case of phenic acid, solutions of 1:1000 had no effect, and even those of 3:100 or 6:100 had a doubtful action, although caustic effects were manifest. Creasote, so much vaunted in tuberculous affections, failed to destroy the bacillus of tuberculosis, even in the proportion of 1 per 1000; and it was the same with quinine. In fine, corrosive sublimate, which has justly been considered as one of the most powerful antiseptics, proved itself without action upon the microörganism of tuberculosis even in the proportion of 1 per 1000.

What do all these experiments go to show? This surely, that the tuberculous element offers an extraordinary resistance to all antiseptic agents, and that, in order to destroy it, you must at the same time destroy the living tissues which are its habitat. In these experiments we must, in fact, carefully distinguish the antiseptic from the caustic action. When you destroy by a physical or chemical agent the elements of a tissue, you thereby abolish its virulent properties; this is, for example, what happens by heat. Hippolyte Martin, in fact, obtained destruction of the tubercle bacillus by heat, and true tubercle was transformed into an inert body when the temperature of 85° C. was exceeded, and this result was the more certainly attained by a temperature of 100° C. and above.

In a manuscript note, which Hippolyte Martin has kindly put into my hands, he signalizes the favorable effects of hydrofluoric acid, which in the proportion of 1 per 3000, and, perhaps, of 1 per 4000, appears to be destructive to the parasite of tubercle. But we must

[1] Hippolyte Martin: On the transformation of true or infectious tubercle into an inert foreign body under the influence of high temperatures and various reagents. Arch. de Phys., 1881, p. 93; Revue de Méd., 1882, t. ii. p. 905, and 1883, t. iii. p. 209.

not, at the same time, forget the extreme causticity of this acid, which acts much more as a destroyer of tissue than as a veritable aseptic.

However, all the experimenters have not arrived at the same conclusions as Hippolyte Martin. Thus it is that Vallin, in the interesting communication made this year to the Academy of Medicine, has shown us that burning sulphur, in the proportion of one ounce to the cubic metre, destroys the virulent properties of tubercle juice. Corrosive sublimate, in the proportion of 1 per 1000, has the same action, but in that of 1 per 2000 it is inefficacious, while nitrosyle, in the proportion of 66 centigrammes per cubic metre, also causes sterilization of tubercle juice. Vallin's procedure was a little different from that of Hippolyte Martin; he made use of strips of filter paper soaked in distilled water; between these strips tuberculous products were crushed, then the paper was dried in the open air, and submitted to the action of divers disinfecting agents; they were finally soaked again in distilled water, and the liquid obtained by expression was injected into the peritoneum of guinea-pigs.

A physician of Allevard, Dr. Niepce, has lately affirmed that sulphuretted hydrogen destroys the bacillus of tuberculosis in the sputa of phthisical patients, and that the sputa thus acted upon become powerless to induce tuberculosis in animals.

A graduate of the school of Montpellier, Dr. Pilate, has repeated, with the aid of Drs. Cavalier and Mairet, the experiments of Niepce, and he affirms that of all the agents with which he has experimented, such as mercuric iodide, corrosive sublimate, helenine, thymol, iodine, carbolic acid, boric acid, the most active is sulphuretted hydrogen. Dr. Sormani and Brugnatelli claim to have obtained an antibacillary action with a certain number of liquids, and even in feeble doses. On the other hand, the experiments made in 1883 by Coze and Simon are absolutely confirmative of those of Hippolyte Martin. These experimenters have divided their researches into three groups. In a first series they mixed forty centigrammes of phthisical sputa, in which they had previously noted the presence of bacilli, with different antiseptic substances; then, after forty-eight hours' contact, they injected these mixtures in guinea-pigs in the region of the groin.

In a second series of experiments they injected only tuberculous matter; then they practised immediately afterward, and for several days in succession, antiseptic injections in the region of the first tuberculous inoculation.

Finally, in the third series of experiments, they endeavored to see if they could arrest the development of the disease in animals already the subjects of tuberculous evolution.

They thus, in their three series of experiments, made trials of bichloride of mercury, eucalyptol, sulphuretted hydrogen, creasote, helenine, thymol, etc. The last two series of researches gave nothing but negative results, and as for the first, creasote alone seemed to them to retard the local development of tuberculosis.

What conclusion shall we draw from all these experimental researches? Must we admit that in man the bacillus of tuberculosis resists all our therapeutic measures? Such a conclusion, gentlemen, would be altogether too premature. These experiments show us that in animals such as the guinea-pig and hare, which present a singularly favorable soil for the development of tuberculosis, our medicinal agents show themselves impotent to destroy the bacillus. But this is not the case with animal species, which offer a better resistance to the bacillus—the dog, for instance—and here we see the bacillary inoculations often fail. It is the same with man, and before the discovery of Koch (as well as since) we were in possession of unimpeachable observations showing the cure of bacillary phthisis. So, while recognizing the useful indications furnished by experimental researches, we must, in order to appreciate their just value, turn to clinical observation.

The discovery of the bacillus, and the experiments which we have just mentioned, indicate to us the therapeutic paths which we are henceforth to pursue, and which comprehend two principal lines of investigation—the one, by which we are to endeavor through medicinal means to oppose the multiplication of bacilli, and the other, by which we seek by hygienic means so to modify culture medium, that it shall be unfit for the habitat of the bacilli.

Prof. Germain Sée, in his work on *Bacillary Phthisis*, has insisted at great length on the new departure which ought to be taken by the therapeutics of tuberculosis since Koch's discovery, and what conditions should be fulfilled by the antivirulent agent, which he calls *necrophytic*.

In the first group of agents, we have chiefly medicinal inhalations, and medicaments which are eliminated by the lungs.

Among the medicinal inhalations, it is substances such as iodine, iodoform, eucalyptol, corrosive sublimate, phenic acid, etc.—in a word, the least irritant antiseptic agents—which should be recommended; and our late venerated master, Piorry, seems to have had prevision of its parasiticide power, when, with such persistence, he insisted on the utility of iodine inhalations in tuberculosis. I believe, also, that iodoform, so much vaunted these late years, may be utilized in these inhalations, being not only a very active aseptic agent, but also a powerful sedative.

You know how these inhalations are practised. They consist in aspirating a current of air through medicinal solutions, and breathing the air thus medicated. A wash-bottle with two tubes communicating with the exterior (one tube dips beneath the liquid), answers the purpose. You can, if you prefer, use the inhaler of Le Fort, of Lille, in which the air penetrates to the liquid through holes in the sides. Le Fort puts into his bottle the following mixture: Camphor, 8 parts; tar, 4 parts; tincture of iodine, 4 parts; Hoffman's anodyne, 1 part. You may also employ some of the more complicated inhalers, in which the air is not aspirated by the patient, but projected upon him by a ventilator operating by clock-work, as in Haro's apparatus.[1] Haro uses iodoform principally, in the pulverization of which it is necessary that the temperature of the mixture should be kept raised. You have seen me use in one of our wards an ingenious vaporizer devised by M. de Linières. This vaporizer, which is put in operation by

[1] Haro: On a New Kind of Inhalations Practised at Amelie les Bains; Bull. de Thérap., t. cvi. p. 409.

Le Fort: On a New Inhaler, and its Action in Pulmonary Affections; Bull. de Thérap., t. ci. p. 342.

a rotatory movement, projects in the ward vapor of water charged with iodoform; but it will take us many months to estimate at their just value the effects of these vaporizations of iodoform upon our tuberculous patients. And now, while on this subject of antiseptic inhalations, I ought to speak to you of the experiments being performed at the present time by my pupil, Dr. Chevy, with hydrofluoric acid, experiments which have been made the subject of his inaugural thesis.

Struck by the results indicated by Hippolyte Martin, demonstrating the remarkable antibacillary action of hydrofluoric acid in tuberculosis, it occurred to me to employ this acid in inhalations; Dr. Bergeron had pointed out the extraordinary effects which he had obtained from the vapors of this acid in the treatment of diphtheria, while Chevy and myself were showing that animals might live without inconvenience in an atmosphere containing 1 part of hydrofluoric acid to 1155 parts of air.

Moreover, a careful investigation made in the great establishments where hydrofluoric acid is used for etching on glass, enabled us to determine, not only that an atmosphere thus charged with hydrofluoric vapors is not injurious to the workmen, but that, on the contrary, individuals suffering from chest affections had experienced favorable effects therefrom; on this point the overseers of the works are unanimous.

We have since then been experimenting by placing our patients in a special ward, of a capacity of about twenty-two cubic metres, in which apartment we vaporized one grain of pure hydrofluoric acid (which would give the proportion of about 1 part to 25,000); the liberation of the hydrofluoric acid is obtained by placing the liquid acid in a small leaden cup heated in a sand bath. Our tuberculous patients remain an hour in this atmosphere. I can say nothing as yet of the results which this experimentation may give; before formulating any positive conclusions these trials must be continued for months and even years.

What I can, however, affirm, is that in the immense majority of cases these inhalations of hydrofluoric acid have not been at all inconvenient to our patients. Some of them have experienced a little irritation in the throat, due to the local action of the acid, but the majority have derived a certain benefit in the way of diminution of the cough and expectoration. I am inclined to think that these inhalations in their application to the treatment of tuberculosis constitute a remedy of much promise.

But permit me, since I am now on the subject of hydrofluoric acid, to say, that of all the antiseptics known, this is, perhaps, the most powerful, and in the experiments which Chevy and I undertook, it required but infinitesimal quantities to arrest fermentation. Pardon, gentlemen, this long digression, but the most of you have followed with interest the experiments to which I have alluded, and I thought it worth the while to sum them up on this occasion. I come back again to my subject, and mention among the means to employ in the treatment of phthisis, antiseptic sprays.

In my opinion these latter are very much inferior to the inhalations, for it is only exceptionally that these pulverizations penetrate to the interior of the lungs. Dr. Miquel, however, claims to have obtained good results in tuberculosis from pulverizations of the following mixture: biniodid of mercury, 1 part; laudanum, 20 parts; distilled water, 2000 parts.

In order to obtain a more immediate action, it has been advised to inject the antivirulent solutions directly into the pulmonary parenchyma. This practice has been attempted in Germany by Heller, who has thus made, in three patients affected with phthisis, intraparenchymatous injections of corrosive sublimate in solution.

In France, Prof. Lepine and his pupil, Truc, have repeated these experiments. This is their manner of procedure: they employ alcohol at 90° containing a variable proportion of creasote, 2 to 4 per cent.; they use for these injections the syringe of Pravaz with the No. 1 needle of Dieulafoy's aspirator, and have already performed twenty-five injections on fifteen patients, introducing each time into the parenchyma of the lungs a quantity of the creasote solution varying from a few drops to fifteen or twenty cubic centimetres.

The results thus far have been uncertain, and in patients affected with advanced lesions they have observed hardly any symptoms of amelioration. Therefore, Lepine and Truc speak very reservedly respecting the definite curative value of these parenchymatous injections, and, for my part, I think that such injections are likely to be more dangerous than useful.

Internally, it is still to such medicaments as creasote, the turpentines, the sulphur preparations, that you will resort; these may render service by their elimination by the pulmonary passages. But whatever parasiticide action these agents may be supposed to possess, they must still yield the palm to the modifiers of nutrition, which render the organic soil unfit for the microbes.

Until by a more exact acquaintance with the bacillus and the conditions of its culture and development, we shall be able, as in the case of anthrax and rabies, to prepare an attenuated virus which, by its inoculation in man, shall preserve him from being the prey to these bacilli, we must direct all our efforts to create in individuals predisposed to tuberculosis a soil unfavorable for the culture of the bacillus. To obtain this result we must utilize two factors: air and alimentation.

Although we have not very precise data respecting the action of the air under different degrees of pressure on the microörganism of tuberculosis, and new researches are needed before we can come to any definite conclusion on this point, we have very good evidence that high altitudes are unfavorable to these bacilli, and even destroy them. The law established by Jourdanet, that at certain altitudes phthisis does not exist, finds a certain confirmation in this fact, that the higher you go, the fewer the microbes you find in the air.

As for alimentation, the method first brought into vogue by Debove has proved to be of the highest utility, and it is to-day generally admitted that, in certain cases where the integrity of the digestive tube is complete, one may, by superalimentation, obtain amelioration and even cure in pulmonary consumption. The important communication of Broca and Wins[1] has given us many conclusive observations to this effect,

[1] Chevy: Thèse de Paris, 1885, and Bull. de Thérap., April 15, 1885.

[1] Broca and Wins: Bull. de Thér., 1883, t. cv. p. 289.

and my pupil Dr. Pennel published in 1882 a series of cases where the beneficial action of this forced feeding was most manifest,[1] and I am astonished that the homœopathic physicians who often give such scrupulously nice attention to the details of their hygienic treatment, have rejected, as Jousset has done, the employment of superalimentation, by powders of meat, for a vegetarian regimen.

I cannot here enter into the details of this superalimentation; you known that, by reason of recent improvements in the manufacture of meat powder, we can now give the latter in chocolate and in syrups, a consequence of which is that we do not now employ "gavage" in pulmonary complaints, reserving it exclusively for patients affected with dilatation of the stomach or persistent vomiting of food. Here, too, I have abandoned the stomach tube which I formerly used, and which goes by the name of "*gaveuse*," for the tube of Debove, which, owing to its resistance and small volume, is introduced without the least difficulty.

What I can affirm, is that in tuberculous patients that have profound and obstinate anorexia, or that vomit their food under the influence of the least effort of coughing, gavage will sometimes give you exceptionally good results. Under its influence the appetite returns, the strength improves, and what is a singular fact, and one not well explained, is that while all food introduced by the mouth is vomited, the alimentary mixtures introduced directly into the stomach by the siphon are well supported, I assign then a preponderant *rôle* to superalimentation in the antiseptic treatment of tuberculosis, and this, because it constitutes, in my opinion, our most powerful means of modifying the culture soil.

As you see now, if Koch's discovery has not already revolutionized the therapeutics of pulmonary phthisis, it has nevertheless enabled us to give a scientific explanation of the *modus operandi* of the greater part of the medicinal agents which we use, and for this very reason it constitutes a step in progress, both from a therapeutic and a prophylactic point of view. This great fact of the contagiousness of tuberculosis is to-day admitted without dispute, and we see on all sides hygienists as well as physicians endeavor to establish on a scientific basis the hygiene of the tuberculous. When you reflect, gentlemen, that at this very time (December, 1885) scarcely three years have elapsed since the discovery of the microbe of tuberculosis, and when you consider the large number of scientific researches and the already voluminous literature to which it has given rise, you cannot fail to entertain with me the hope that the day will come when, better enlightened as to the life history and mode of development of the bacillus, we shall be able to destroy it in the living organism, or at least attenuate its effects.

ORIGINAL ARTICLES.

A YEAR'S WORK IN LAPAROTOMY.

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

DURING the past year I have had forty-four cases of laparotomy, with four deaths, as follows:

	Cases	Deaths	Recoveries.
Ovariotomy	28	2	26
Oöphorectomy	9	1	8
Hysterectomy	2	1	1
Exploratory incision	4		4
Pelvic abscess	1		1
Total	44	4	40

Of these forty-four cases, twenty-five were operated on in my private infirmary, with two deaths; twelve were operated on at the Hospital of the University of Pennsylvania, with one death; and seven were operated on at the home of the patients, with one death. Of these four deaths only one was due to septicæmia, and that, a case of oöphorectomy, occurred in a private room at the Hospital of the University. It was, I think, in no wise due to hospitalism, but to the adverse complications of the case. The ovary and oviduct were filled with pus, and so matted by inflammation to adjacent structures that only a portion of them could be removed, and that in fragments. The pus unavoidably escaped into the abdominal cavity, which was carefully cleansed and a drainage tube put in, yet a fatal inflammation set in. Another death was due to shock after the removal of the womb containing a fibroid tumor with universal adhesions, and weighing seventeen pounds, The two deaths after ovariotomy were not due to septicæmia, and are somewhat mysterious. Case 139 was operated on at her home in Bedford, Pa., and I did not see her again. The cyst was parovarian, weighing forty-three pounds, and both ovaries were removed. There was not an adhesion, and the operation was a very easy one. For twelve days she did perfectly well; the stitches were removed and the bowels opened. Then an obstinate vomiting set in, which ended her life on the seventeenth day. No autopsy was permitted, but six months before the operation she had had an analogous attack of vomiting, which nearly killed her—her physician, an able practitioner, having, in fact, given her up. In Case 156 death resulted from a supposed attack of malaria. Both ovaries had been removed, the larger one weighing about thirty pounds. There were omental adhesions and very firm ones to the abdominal wall, needing a number of ligatures. She recovered promptly from the operation, the wound united, the stitches were removed, and she was allowed to sit up out of bed. In short, she seemed so certainly convalescent, that I reported her as my twenty-fifth consecutive case of ovariotomy with but one death. On the seventeenth day malarial fever, to which she was subject, set in with bilious vomiting, and, in spite of all I could do, she died rather suddenly on the twenty-first day, with symptoms of heart-clot.

In Cases 136, 138, and 140 the cysts had burst a few hours before the operation, and, although the peritoneum seemed thickened and injected, no bad results followed. In Case 148 the cyst had burst fifteen times, and had been tapped twice before the operation. The tumor was a suspicious-looking thin-walled multilocular cyst of the left ovary. Some of the cysts were filled with pus, others with a clear fluid. The right ovary, which was as large as an apple and filled with a colloid material, burst while

[1] Pennel: Alimentation in Phthisis, Bull. de Thér., t. cii. p. 85.

being removed, and its contents escaped into the abdominal cavity, yet the patient recovered promptly without the use of a drainage-tube. Let me here say that, in my opinion, the danger attributed to the escape of the contents of an ovarian cyst into the peritoneal cavity is much overrated. For instance, some German ovariotomists never use a trocar. They simply incise the cyst, letting the contents fly where they will, and, of course, some must get into the abdomen however it may be protected. So often in my hands has this happened from the bursting of cysts during the process of breaking up adhesions, that I have ceased to be disturbed by the accident. It always necessitates a more careful sponging out of the peritoneal cavity, and, in case the escaping fluid is purulent, a drainage-tube should be used.

There is another point on which my experience may be of value to others, and that is, that Monsel's solution of iron can be applied with impunity to large oozing surfaces. But there must not be a redundancy of the fluid, and it should be applied either by the tip of the finger wetted with it, or by a small sponge well squeezed out. Although appearances are against its use, the blackened and charred-looking flesh does not appear materially to add to the risk of the operation, and it is a great comfort to operators to know this.

From the seventeen cases of double ovariotomy it will be seen that I still adhere to removing the second ovary in women who are near the climacteric, or who have passed it, and always in younger women if it exhibits any trace of disease. I am led to this because there is undoubtedly a great tendency for the second ovary to take on cystic degeneration. It will be observed that in Case 142 I had removed the right ovary four years previously, from a lady aged forty-two. There was not the slightest chance of her ever becoming pregnant again, and I think that, considering her age, the left ovary, however healthy, should have been removed. Early in 1885 it began to enlarge very rapidly, giving the lady much mental and physical distress. In fact, I never saw a patient suffer more from an ovarian cyst. Great abdominal pain and constant nausea and vomiting were the prominent symptoms. For these I had to empty the cyst twice by aspiration. The first time, on March 9th, great relief followed for a few days; the second time, on April 1st, nothing whatever was gained, and I was compelled to operate while she was in a desperate condition of weakness from excessive vomiting. For two days there was a lull in the symptoms, then the old stubborn vomiting set in, which now rapidly reduced her. It was finally controlled by very large doses of calomel—fractional doses not having succeeded. The lady eventually got well, but her nervous system has received a shock from which she has not yet recovered, and perhaps never will. Year before last, I had to remove the second ovary from a woman advanced in life, from whom I had removed an ovarian cyst four years before. Both cysts were colloid, and I believe, from the general infection of the abdominal cavity, that the second one was malignant. The woman died on the fourteenth day from progressive exhaustion, and I cannot but think that, had both ovaries been removed at the first operation, she would still be alive. These two cases, therefore, incline me to consider that, other things being equal, it is erring on the safe side to remove both ovaries.

With regard to papillomatous cysts, I have about made up my mind to consider all benign, until the subsequent history determines otherwise. Cases 136, 138, and 140 exhibit remarkable groups of papillary growths. In the former the whole abdominal peritoneum was studded with them; yet the three patients did well, and have since kept extremely well. In fact, I cannot now recall a case of papillary degeneration which turned out to be malignant. Papillary growths, however, tend to weaken or destroy the wall of the cyst at some point, and these are the cysts which so often burst either before or during their removal. In each one of the cases here referred to, the cyst had burst some days before the operation.

With regard to malignancy, I am sure that Case No. 149 was an example. Both ovaries were similarly affected with a racemose variety of cystic degeneration—that is to say, the cysts were all small, but distinct and separately attached to one common stalk, like a bunch of grapes. The microscopic examination did not reveal either the cells of sarcoma or of carcinoma; yet, from the macroscopic characteristics of the twin growths, I was very confident of their malignancy. The subsequent history confirmed this opinion, for while she recovered promptly from the operation, and for a few weeks was much better, her health unaccountably began to fail, and she died four months later from otherwise inexplicable exhaustion. Malignancy occasionally lurks insidiously in the most benign-looking cysts. A little more than a year ago I removed an adherent cyst which did not arouse the slightest suspicion of malignancy. Lately the lady has presented herself with an epithelial cancer in the upper angle of the incision, which was a long one. In my first case of ovariotomy the same thing happened, the woman dying a year later from malignant disease of the cicatrix.

It will be seen that the proportion of difficult cases was a large one. In some the difficulties to be encountered were apparent beforehand; yet in not a single instance have I declined to operate on account either of the low condition of the patient or of the dangerous character of the adhesions. Out of the twenty-eight cases of ovariotomy there were twenty-one with adhesions. In four of the latter the adhesions were universal, in eight more they were intestinal, and in three they were uterine. Case 135 was perhaps the most difficult operation I ever encountered, and I cannot to this day say whether the tumor was ovarian or not. The cyst was so universally adherent to intestine, womb, bladder, liver, and stomach that it did not have a square inch of unattached surface. It was slowly enucleated, and removed without a pedicle; but very many ligatures were needed. During this process the bladder was torn. The rent was secured in the lower angle of the abdominal wound, and a drainage tube put in; but an urinary fistula is now present, which will have to be operated on at some future time. This case I did

not expect to get well; indeed, I thought that the shock would destroy life in a few hours. A very large number of ligatures were needed in Cases 133, 134, 135, 146, 151, 153, and 156. No. 156 was the only one of this group that died, not from septicæmia, but from malaria, as I believe. Over thirty ligatures were used in Case 153. The adhesions were parietal, intestinal, and omental; she had been tapped nine times, the tumor weighed seventy-five pounds, and a drainage tube was put in; yet she recovered without a bad symptom. The only way that I can explain why the proportion of cases with adhesions is so much larger than in those reported by European operators, is, that physicians in this country are not yet educated up to the idea of an early performance of the radical operation, and that the women themselves not only put off the evil day, but they often insist upon being tapped—an operation which is very likely to be followed by adhesions.

In the successful case of hysterectomy, a tumor, weighing eight pounds, was removed, together with a portion of the enlarged womb. As the uterine cavity was not invaded, the pedicle, which was as large as one's wrist, was transfixed, tied, and dropped. No bad symptoms followed. This operation was performed at the hospital of the University of Pennsylvania.

The four exploratory incisions were made with the view of removing the ovaries, on account of fibroid tumors of the womb. But in each case the tumor was so fixed by adhesions that the ovaries could not be reached, and the patients had previously stipulated that in that case the uterine growth was not to be removed. Two were performed at my private hospital, and two at the University.

In the case of laparotomy for pelvic abscess, a patient of Dr. W. Sinkler's, pus had been escaping for three years into the bladder and rectum, and the lady was bedridden. As the abscess was always kept empty by these two outlets, fluctuation could not be detected in the plainly thickened, broad ligament. I therefore decided to open the abdominal cavity and the abscess, then stitch its walls to the wound in the belly, and put in a drainage tube. When, however, the abdominal cavity was exposed, the pyogenic body was found to be not larger than a small apple, and its walls therefore could not be raised up and stitched to the edges of the incision. Guided by the hand in the peritoneal cavity, I was able to penetrate, *per vaginam*, the centre of the abscess with the closed blades of a sharply pointed pair of scissors. This opening was now enlarged by my slender uterine dilator, and a flexible catheter put in. While the patient has not been wholly cured by the operation, she has been vastly benefited.

The consideration of my nine cases of oöphorectomy will be reserved for another paper. I will merely say here that four of them were performed for ovaralgia, three for bleeding fibroids, one for epilepsy, and one for a menorrhagia, which had resisted every known therapeutic measure.

In conclusion, let me say, with regard to the technique of the operation for laparotomy, that I use the ordinary knot and the Staffordshire knot indifferently; that I now, in the long incisions, cut directly through the umbilicus, instead of going around it; that I include the recti muscles, and all the tissues in the abdominal sutures; and that, while not a very firm believer in the spray part of antiseptic surgery, I used the atomizer in every case but No. 159, and that this patient did as well without it as most do with it.

THE DISINFECTANT VALUE OF STANNOUS CHLORIDE ($SnCl_2$).

EXPERIMENTS CONDUCTED IN THE BIOLOGICAL LABORATORY OF THE JOHNS HOPKINS UNIVERSITY.

BY A. C. ABBOTT, M.D.,
OF BALTIMORE, MD.

IN view of the objections to the use of mercuric chloride as a disinfectant and an antiseptic, it has been our aim in some recent studies to find a relatively harmless substitute for it.

Not only is mercuric chloride a dangerous poison when taken internally, but it has also been shown to exert a very detrimental action upon lead pipes when brought in contact with them, as is necessary in the disinfection of water-closets. Moreover, several reports have lately come to our notice of its toxic effects having been produced even when used in the very dilute solutions employed in antiseptic surgery and in obstetric practice.

It was hardly with the hope of having found a substitute devoid of these objections, and at the same time possessing an equal potency as a germicide, that Dr. J. R. Duggan, of the Johns Hopkins University, recently suggested to me the advisability of making some experiments upon stannous chloride ($SnCl_2$), with a view of determining its influence upon living organisms. The analogy of its chemical composition to that of mercuric chloride, its lack of poisonous properties, its non-corroding action on lead pipes, and the cheapness of its preparation, at once recommended it as being possibly the substance for which we were seeking. Accordingly, a series of experiments were begun.

A solution of the salt of known strength having been made, its germicide value was determined after the same method as has been adopted in all of our work on commercial and other disinfectants. The salt under consideration came far short in its germicide value of mercuric chloride—far short, in fact, of what we had expected—yet the evidence of its possessing a higher potency in this capacity than many other substances commonly employed for the same purpose, together with the points above enumerated in its favor, we think sufficient to justify us in recommending it for general use

Our experiments show that stannous chloride, when in contact with spores in decomposing organic matter, kills them at 1 per cent. after an exposure of two hours, and that it failed to disinfect the mass when present in 0.8 per cent. after the same length of time. Comparing these figures with those indicating the potency of zinc chloride, copper sulphate, zinc sulphate, and ferric sulphate, which are the salts most generally used for the purpose of disinfection, we find the first of these, zinc chloride, to be active in 5 per cent., and inactive when present in 2.5

per cent.; while the last three—copper sulphate, zinc sulphate, and ferric sulphate—we find to be inefficient respectively in 20 per cent., 40 per cent., and in saturation. These facts, taken in conjunction with the moderate cost of stannous chloride, and its entire inactivity on lead pipes, are sufficient to indicate a large field of utility for this compound. Moreover, when taken internally, it has no more deleterious effects than the salts of copper, zinc, or iron.

We might here state that in making a solution of stannous chloride intended for permanent preservation, it is advisable to add an equal weight of ammonium chloride; this prevents the formation of the insoluble oxychloride of tin, which would otherwise be deposited upon standing.

At the suggestion of Dr. Duggan, similar experiments were instituted with the stannate of potassium; but our report in this regard is less favorable than upon the stannous chloride. This substance having shown itself to be inefficient as a germicide, in a 3 per cent. solution, we concluded to pursue the investigation no further, as the compound could, under these circumstances, be of no practical value in this capacity, and especially as the expense attending its manufacture is much greater than that of other substances which occupy a higher place in the scale of disinfectants.

MEMBRANOUS CROUP; TRACHEOTOMY; RECOVERY.

BY JOHN D. NEET, M.D.,
OF VERSAILLES, KY.

THE following case of tracheotomy for croup is chiefly reported for its statistical bearing.

On the evening of Nov. 13, 1885, I was summoned to see Annie H., æt seven years, suffering with membranous croup. Five days previously (Sunday) she manifested the usual symptoms of acute catarrhal laryngitis. On Tuesday she was quite hoarse, cough dry and stridulous, and respiration labored. During the time she was under the charge of two other physicians, who had faithfully administered the usual treatment for croup. In response to the urgent request of the little patient, I assumed management of the case on Friday evening.

On examination I found the fauces and pharynx very much congested, but free from membranous exudation, nor was there any enlargement of the cervical glands. Pulse 110; temp. 99½°; expectoration scanty; respiration stridulous and difficult. The treatment by mercurials having been ineffectually tried, I prescribed the ammonia and potash preparations, with counter-irritation and flaxseed poultices over the larynx, and impregnated the air of the room with steam from strong lime-water. The dyspnœa and cough grew worse toward morning, and an emetic was administered. This, with the violent coughing, caused the expulsion of a piece of tough membrane five-eighths of an inch long, and one-fourth of an inch wide.

Nov. 14.—9 A. M. Pulse 104; temp. 91°; respiration less difficult; treatment continued. 6 P. M. Pulse 110; temp. 99½°. Emetic administered, but symptoms unimproved.

15th.—Condition during the night and day unchanged.

16th.—9 A. M. Patient worse. Pulse 120; temp. 99½°; respiration more labored and difficult. 8 P. M. Patient unable to lie down. Pulse 130; temp. 100°; beginning cyanosis about the lips: cough constant, dry and stridulous; marked dulness at the base of right lung, and crackling râles throughout both lungs. All treatment having failed, it was now evident that tracheotomy was the only available source of hope. Drs. Skillman and Scott, of Lexington, were called in consultation, and besides concurring in the opinion that tracheotomy was imperative, rendered valuable assistance at the operation.

17th.—2 A. M. Pulse 200; physical signs of pulmonary œdema present, countenance of a bluish-ashy hue, and exhaustion pronounced. Chloroform was administered, and I proceeded at once to open the trachea. Hemorrhage was free, but entirely venous. There was no delay on account of the bleeding, but the trachea was opened at once, whereupon the patient coughed and expelled through the opening a piece of false membrane one inch and a half long, and half an inch wide. The moment the tube was inserted the hemorrhage ceased. In fifteen minutes thereafter the pulse had fallen to 150, respiration 40, and easy. In thirty minutes the pulse was 138, and the patient removed to bed.

8.30 A. M. Patient had a paroxysm of coughing, and the tube became obstructed with false membrane. The inner tube being removed, with Trousseau's tracheal forceps I extricated a large mass, in pieces, of false membrane, and the patient sank into a restful sleep.

11 A. M. Patient has taken four ounces of milk. Pulse 128; temp. 99⅘°; respiration 30.

6 P. M. During the day with each paroxysm of coughing, small pieces of membrane were expelled through the tube. The inner tube required to be removed every hour in consequence of occlusion by tenacious mucus and small particles of false membrane which could not be removed with a feather. Pulse 120; temp. 99½°; respiration 28; crackling râles less abundant, and dulness at base of right lung disappearing.

7 P. M. Another paroxysm of coughing, and tube choked with false membrane. With Trousseau's forceps a still larger mass of membrane was removed.

18th.—7 A. M. In consequence of the cough and occlusion of the inner tube, requiring its removal every half hour, the patient slept very little last night. Pulse 116; temp. normal; respiration 28; dulness at base of right lung disappeared, yet there are a few crackling râles present. Patient drank two glasses of milk during the night.

7 P. M. Patient fretful all day. Pulse 125; temp. 100°; respiration 35; cough almost constant, secretion through tube less, dulness with crepitation in lower lobe of right lung.

8 P. M. Another violent paroxysm of coughing, in which death seemed imminent from suffocation. A piece of false membrane two inches long, and half an inch wide, removed through tube. Administered

twenty grains of calomel. Patient passed into a quiet sleep.

19th.—9 A. M. Patient had a more comfortable night; cough not so troublesome. Calomel acted freely. Pulse 115; temp. 98⅘°; respiration 26. The dulness with crepitation in the right lung has disappeared.

6 P. M. Pulse 112; temp. normal, respiration 26. Secretion through tube now thick and yellow, showing the detritus of the disintegrating membrane. Ten grains of calomel administered.

20th.—9 A. M. Pulse 108; temp. normal; respiration 25, and lungs clear throughout. Patient takes nourishment freely.

6 P. M. Pulse 103; respiration 26. Ten grains of calomel

21st.—9 A. M. Patient slept well last night. Pulse 100; respiration 24.

6 P. M. Condition the same.

22d.—Condition about the same throughout the day.

23d.—9 A. M. Pulse 96; temp. normal; respiration 24. Inner tube closed by a small cork, and as the patient breathes well *per vias naturales* it is allowed to remain.

24th.—Patient having suffered no distress with tube corked, the tube is now removed, and over the wound is placed a bandage of cheese-cloth attached to oil-silk.

5.30 P. M. Patient breathes partially through larynx, and tracheal opening half closed.

25th.—Wound closed.

26th.—Patient up and dressed, aphonia subsiding, and wound healing nicely.

Dec. 2.—Wound entirely healed, and patient discharged.

The after-treatment of the case can be summarized in a few words. The temperature of the room was constantly maintained at 80°, and the traditional steam kettle dispensed with as useless. Repeated doses of calomel were administered for its alleged effect upon membranous exudations. While physical examination of the lungs pointed to the probable early accession of pneumonia, none of the usual remedies were resorted to for the relief of this condition; for it was regarded as the effect of mechanical obstruction in the larynx preventing free access of air to the lungs, and upon removal of the cause we expected the effect to cease without recourse to therapeutic measures.

We find, from the clinical history, that the dulness of the lung had disappeared twenty-nine hours after the operation, but in *twelve* hours later, there was a reappearance of the physical signs of pneumonia. During the twelve hours preceding the accession of the pulmonary symptoms the patient had been coughing almost constantly in the effort to expel a foreign substance (false membrane). This being removed, in twelve hours more the physical signs of pneumonia had again disappeared. From the facts it seems proper to conclude that the detached membrane within the trachea, acting mechanically and exciting irritation, stood in a causative relation to the development of the pulmonary symptoms; for after it was extricated the lung soon resumed its normal condition.

It is conceded on all sides that the success of tracheotomy for croup depends preëminently upon the close and unremitting attention of the surgeon, with scrupulous care in the various measures comprised under *good nursing*, and to which his personal attention should be given. For, amid the perplexing emergencies which are liable to arise at any moment from detached membrane or occlusion of the tube, it is a hazardous experiment to entrust the necessity for prompt and judicious action to an inexperienced hand. The span of a few seconds may prove the measure of our opportunity, so that, with a concientious regard for the best interests of the young life entrusted to his professional skill and keeping, and imbued with an earnest desire to lend his efforts toward elevating the operation from that opprobrium into which its high mortality-rate has placed it, it devolves upon the surgeon as his paramount duty to give that personal attention—even to the total neglect of other business—which the direful emergencies of these cases necessitate. The human interest demands this—the scientific interest calls loudly for it; and he, who cannot thus briefly sacrifice his outside interests, should not abuse the privilege and power which his high vocation reposes in him, by imperfectly doing that which ought to be done well.

MEDICAL PROGRESS.

ALBUMINURIA OF PREGNANCY AND ECLAMPSIA.—DOLÉRIS and POUEY have studied in collaboration the relation of microörganisms to the albuminuria of pregnancy, and have arrived at the following conclusions:

1. Microörganisms are to be found in the bladder in these cases independently of albuminuria, and apparently unconnected with any kidney trouble.

2. Albuminuria is present in about five per cent. of pregnant women, and in such urine microörganisms, especially streptococci, are always present.

3. The blood of such women usually, if not always, contains bacteria, the presence of which is demonstrable by culture.

4. In the cases of albuminuria of pregnancy with eclampsia, microörganisms were present in both blood and urine, and apparently had a direct quantitative relation to the severity of the convulsions.—*Centralb. f. klin. Med.*, Dec. 26, 1885.

DILATATION OF THE UTERUS.—VULLIET has made a communication to the Medical Society of Geneva regarding a new method of permanently dilating the uterus. This operation, which he has performed successfully for over a year, permits the inspection and study of the uterine cavity even during menstruation, and is so complete that casts and photographs of the interior of the uterus have been taken.

The female is placed in an exaggerated genupectoral position and the dilatation is begun by the successive introduction of urethral sounds. This is succeeded by the introduction of small tampons of iodoform wadding, the number of which is gradually increased, and which are permitted to remain in place for forty-eight hours. Occasionally a piece of laminaria is introduced, never

longer than twenty-four hours, and it is immediately replaced by iodoform cotton. At the end of a period varying from ten to twenty-five days complete dilatation is obtained.

In the thirteen cases in which Vulliet has performed this operation no ill result, apart from occasional temporary uterine colic, has ensued. The clinical indications for this procedure are evident, inasmuch as by its means the direct treatment of uterine neoplasms is rendered practicable.—*Revue de Thérap.*, Jan. 1, 1886.

The Alleged Fragility of the Bones of General Paralytics.—Dr. T. Christian, Physician to the National Asylum of Charenton, states that as a result of the study of the available statistics, and of personal observation of about 250 general paralytics, that general paralysis does not in itself entail any increased fragility of the bones, and that when osteomalacia is present in these cases it is a purely accidental phenomenon the result of other causes.—*Journal of Mental Science*, Jan. 1886.

Passage of Pathogenic Microbes from Mother to Fœtus.—The continued observations of Koubassoff, reported in *Comptes Rendus*, ci., have given the following results:

1. The anthrax bacilli always pass to the fœtus.
2. The longer the period between the inoculation and death of the mother, the more numerous the bacilli found in the fœtus.
3. More bacilli of the virulent than of the attenuated anthrax virus thus pass over.
4. Maternal inoculation with very strong anthrax vaccine nearly always produces the death of the fœtus.
5. The inoculation with virulent lymph of a pregnant animal which had previously been vaccinated with the attenuated virus is nearly always fatal to the fœtus, and offspring which have survived such maternal inoculation themselves succumb to similar inoculation after birth. In other words, the fœtus is never sufficiently vaccinated through the mother.—*Centralb. f. d. med. Wiss.*, Jan. 9, 1886.

Elimination of Arsenic by the Mammary Gland.—Brouardel records a recent case of poisoning in which a wetnurse was the victim and in which the infant at the breast also succumbed. From the body of the child five milligrammes of arsenious acid were obtained. An experimental verification of these results was obtained by Pouchet in the examination of the milk of some nurses in the Hôpital Saint-Louis, who were under arsenical treatment with Fowler's solution. One of them, who received during one week eight milligrammes of arsenic daily, yielded milk which was shown on chemical analysis to contain in each 100 grammes one milligramme of arsenic.—*L'Union Médicale*, Jan. 3, 1886.

Route Pursued by Inoculated Tuberculosis.—At the session of the Academie des Sciences of December 28, 1885, M. E. Colin presented an account of his experiments on the effects of the inoculation of tubercle in various domestic animals.

He finds that before becoming a visceral affection, tuberculosis constantly attacks the lymphatic system. Instead of being generalized, the first lesion is one of that part of the system in which the foreign matter in question is absorbed, and that such lymphatic tuberculization progresses regularly until the tuberculous matter reaches the general circulation.—*Progrès Médical*, Jan. 9, 1886.

Conditions under which the Blood Coagulates in Living Vessels.—As an addendum to his previous communications on sanguine concretions, Hayem writes as follows to *L'Union Médicale* of Jan. 7, 1886:

In order to demonstrate that stagnant blood may become coagulable while still in contact with the living vessels if the plasma become altered, the jugular of a dog is exposed and ligated in two places in such wise that the portion thus included shall be distended with blood. Into the saphenous vein are then injected a few cubic centimetres of canine serum, and immediately thereafter the other jugular is ligated in a manner similar to the first. At the end of from half an hour to an hour, upon opening the two jugulars, it is found that the blood included between the first two ligatures is fluid, while that similarly treated on the other side has formed a complete clot.

Chloroform Water as a Hæmostatic.—Spaak, of Brussels, recommends the use of a two per cent. aqueous solution of chloroform as a hæmostatic, especially in operations in oral surgery. Its action is very rapid and simple. Washing out of the mouth is said to be sufficient to arrest bleeding even of the large vessels. *Medicinisch-Chirurgisches Centralb.*, Jan. 1, 1886.

Relation of Hepatic Stimulants to the Formation of Urea.—In an elaborate article in the *Journal of Anatomy and Physiology* for January, 1886, Dr. D. Noel-Patton thus summarizes the results of his experiments on the relationship of urea formation to bile secretion:

1. *Salicylate of Soda.*—(A) *In man.* In dose of 0.106 grm. per kilo, salicylate of soda causes no change in the amount of water passed, a slight increase in the urea and a very marked diminution in the uric acid excreted. This last change is by far the most manifest; in one experiment the diminution was as great as 64 per cent.

(B) *In dogs.* In doses of from 0.45 grm. to 0.6 grm. per kilo, salicylate of soda caused a marked diminution in the water passed, a rise in the urea, and a very great diminution in the uric acid excreted.

2. *Benzoate of Soda*, in doses of from 0.51 to 0.58 grm. per kilo, causes little or no change in the amount of water. The urea is greatly increased and the uric acid is diminished, though not so markedly as with salicylate of soda.

3. *Colchicum*, in doses of 0.02 to 0.037 grm. per kilo of the acetic extract (B.P.) causes a very marked increase in the urea and uric acid. When the doses are small the water is also increased, but with large doses the water secreted may actually fall, while neither the urea nor the uric acid are so markedly increased as with smaller doses.

4. *Perchloride of Mercury*, in doses of from 0.0015 to 0.0075 grm. per kilo, causes an increase in the excretion of water, urea, and uric acid.

5. *Euonymin*, in doses of from 0.04 to 0.10 grm. per kilo, causes a slight increase in the water excreted, and a very marked increase in the urea and uric acid. In larger doses, 0.16 grm. per kilo, it causes purging, with no diminution in the water passed by the kidneys, but without the marked rise in the urea excreted.

We thus see that in dogs, in a condition of nitrogenous balance, stimulation of the flow of bile by means of these drugs is accompanied by an increased urea production.

That an increased production and not merely an increased excretion of urea occurred, is clearly shown by the fact that, after the administration of the drug was stopped, the amount of urea merely returned to the normal and did not manifest a fall corresponding to the initial rise.

I would, therefore, conclude that the formation of urea in the liver bears a very direct relationship to the secretion of bile by that organ. On the nature of this relationship I have not touched in the present paper, but at an early date I hope to give the results of a series of experiments upon this subject.

To the physician the results of these observations must have considerable interest, especially of those which, dealing with the influence of salicylates and benzoates upon the uric acid excretion, afford a key to their mode of action in gout. No less interesting is the demonstration of the fact that colchicum increases and does not diminish the production of uric acid.

A RECENT STUDY OF NUX VOMICA.—At a late meeting of the Philadelphia County Medical Society, DR. JOHN H. MUSSER presented a paper "On the Influence of Age on the Dosage of Nux Vomica, with some Remarks on its Therapeutics," in which he says:

Going over the notes of some fifty cases, I find that at from 15 to 40 years of age 45 drops or more of the tincture were almost invariably well borne. After 40 years it was the exception to be able to increase the dose over 35 drops without causing disagreeable symptoms.

One of the patients, aged 24, took 200 drops three times daily with most decided benefit. To another, aged 16, 125 drops were exhibited without experiencing any bad effects. On the other hand, a male, aged 60, could take but 20 drops, and not one over 50 could get beyond 35. Patients aged 16, 24, 28, 35, and 40, took 40, 55, 30, 45, and 45 drops respectively before any therapeutic benefit could be seen.

Two effects of large doses of the drug were observed, that, under certain circumstances, would be disadvantageous,—the production of diarrhœa and of frequent seminal emissions. Small doses of laudanum would readily control the former, although it is rare that the case would demand such very large doses. The latter symptom could not well be remedied.

In mental and physical depression due to prolonged excitement this drug is of value. One of my students took from 600 to 800 drops of the tincture daily, and thereby successfully tided himself over a period of great strain. In fact, he studied harder and kept later hours than at any other examination period, and with less detriment to his health. He is myopic and astigmatic, and this was the first time he came out of his studies without suffering from eye-strain. The doctor writes me that he has used the drug since, in practice, under similar circumstances. For instance, he helped along well a young society girl, who was unusually busy with engagements, until the rush was over. These uses of the drug are as dangerous, however, as those of any stimulant, and it should be given only on extraordinary occasions for the purpose indicated. Its use as above serves to show its power as a nerve stimulant.

It has recently been the custom of students of medicine to take caffeine to keep them awake for study. My observation of the students who had taken one of these drugs was favorable to the use of nux vomica. The ones who took it came off with much better health and less nervousness than the caffeine-eaters.

The following are some of the conclusions which may be drawn from the above statements:

1. The effects of nux vomica are in inverse proportion to the age of the patient; the susceptibility increasing with the age.

2. The usual doses of the tincture indicated in the text-books are inadequate for many practical purposes, and do not represent the usual dose of strychnine.

3. It is a powerful and rather transient stimulant.

4. The best therapeutical effects can be secured in many cases only by pushing the drug almost to the physiological dose.

5. The system soon becomes accustomed to its use, and the dose must be increased.

6. The good effects in dyspepsia are largely due to its power to heighten reflex excitability.—*Therapeutic Gazette*, Jan. 15, 1886.

RELATION OF PRECOCIOUS AND TARDY MENSTRUATION TO THE DEVELOPMENT OF THE FŒTUS AT TERM.—NEGRI, after a study of the data of some twelve hundred labors, concludes that the maximum development (in point of size and weight) of the fœtus at term is found in primiparæ who began to menstruate between the ages of thirteen and seventeen years. Less development of the fœtus is found in primiparæ who menstruated after seventeen years, and the minimum, both in size and weight, in the offspring of primiparæ who menstruated before attaining the age of thirteen years.—*Gaz. Méd. de Paris*, Dec. 19.

TESTS FOR LEAD IN SOLUTION.—Cases are not rare where the presence of lead in water has been exceedingly harmful. When suspected the following will be found efficacious: A very delicate test for lead is by the direct addition of a small quantity of hydrosulphuric acid. This is applicable where a solution is to be tested for lead only. The hydrosulphuric acid produces a black precipitate, if lead is present in large quantities; if in small quantities only, a brownish tint to a dark coloration. This test is of special use in detecting lead in waters used in the manufacture of beverages, which it frequently contaminates, because of the abundant use of lead in the form of pipes and solder, and the presence of which in any proportions renders the water deleterious. Another method for detecting lead that has been dissolved by the corrosive action of water is by the addition of a drop or more of an aqueous solution of cochineal, and if lead is present, even in very minute proportions, a fine violet coloration will be produced. Cochineal will give this test in any solution of lead, provided it is strictly neutral in reaction, but fails in an acid solution.—*Pharmaceutical Record*, Jan. 15, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 30, 1886.

IS AMYLOID DEGENERATION CURABLE?

As is well known, the duration of life in amyloid degeneration of organs is very variable, but, once established, an actual cure is regarded as impossible. When suspected, and recovery occurs, a reasonable doubt may be entertained as to the correctness of the diagnosis.

The possibility of cure has recently been urged by LITTEN, at the Berlin Medical Society, partly on clinical, partly on experimental grounds. Recovery has been seen in cases in which the visceral enlargements and the state of the urine, in association with syphilis or bone disease, left little doubt as to the actual condition which had existed, though in these instances, of course, a positive diagnosis could not be reached. Then, again, there were cases in which the clinical features of the disease were well marked, and the organs after death presented all the characters of the amyloid change, save in the absence of the special reaction to iodine and methyl-violet. Such instances seem to point to differences and changes in the amyloid substance, which may ultimately be detected by other reagents than those at our command at present. He referred to four such instances, which had been under the care of Friedreich. To test the possibility of the absorption of amyloid matter, he introduced small portions of amyloid liver into the peritoneal cavity of guinea-pigs, and found, after some months, that the tissue had so far changed that the reactions were no longer characteristic. It is possible that such gradual changes may also take place in the human body when the symptoms of amyloid degeneration disappear.

In the discussion which followed, VIRCHOW criticised these views very strongly and held that there are no grounds for supposing that, when once present, the amyloid matter can be removed. The degeneration is in reality a substitution of this material for the protoplasm of the affected tissues, and the elements involved cease to have organic structure. We cannot imagine its absorption without actual defects or spaces being left. A small vessel in a state of amyloid degeneration was compared to a tube of ice and the absorption of the amyloid would be like the melting of the tube—nothing would be left of the one or of the other.

Certainly the evidence is not yet forthcoming to show that this serious form of degeneration is ever curable, but we do meet with cases in which, under treatment, the condition becomes much ameliorated and the organs affected reduced in size. In syphilitic patients particularly, the disease may exist for years and present many variations in its progress. While it is possible that in some of these cases the process may be arrested, the reduction in the volume of the liver and spleen, which is regarded as the chief evidence in favor of the absorption of the amyloid matter, may depend on a change in elements other than those affected with the degeneration.

CENTRAL RUPTURE OF THE PERINEUM.

CHARPENTIER has, in the November and December numbers of the *Archives de Tocologie*, an interesting contribution upon central rupture of the perineum, and to some of the points presented by him we wish to call attention.

We have been especially impressed with the decided endorsement which this distinguished obstetric teacher gives to the views of Fabbri, published in 1857, and since upheld by Sabatier, by Boissard, and by others, that the bony pelvis, to which soft parts are added, continuing its canal, and forming its floor so as to constitute the obstetric pelvis, is actually a cylinder. The coccyx is at the fundus of this cylinder, and the vulva is an opening upon its anterior wall; according to Sabatier, "the fœtus in traversing this cylinder describes, by the movement of its centre, a line of progression, subdivided into a line of engagement, of descent, and of disengagement. The line of descent, or practical axis, or directing line, is a straight line as is the axis of the anatomical pelvis." Nevertheless, he holds that this line is not confounded with the anatomical axis of the pelvis, for it is not contained in any position whatever in the antero posterior median plane, but varies according to the position, and according to the variety of the position. "There is not, then, a unity of the practical axis, but a plurality, because this line depends not on the form of the basin, but upon the situation of the presentation in this or in that part of the pelvis, as then, from a dynamic point of view, it necessarily occupies one or the other side of vacant spaces.

"For the accoucheur the normal pelvis ought to be theoretically considered as the union of two cylinders with an elliptic section, united together at the anterior part, and encroaching more and more upon each other as they are considered at the lowest part. They are divided at the fundus by a rather abrupt bend into two portions, one vertical, which corresponds to the engagement and descent, the other horizontal, which is that of disengagement."

It is obvious, from this presentation, that the head descends in a straight line to the perineum, and then turns at nearly a right angle to escape from the vulval orifice. But if the perineum, either from structure or form, does not furnish suitable resistance in force or direction, the disengagement cannot occur normally; the driving, the propulsive force of uterine and abdominal contractions sends the head directly down upon the pelvic floor, and the resistance of that floor ought to direct it in the axis of the obstetric outlet, but this directing power fails either from want of strength in the perineal tissues, or from the vulval orifice being high up, or, in other words, from the great length and obliquity of the perineum. Under such circumstances the fœtal part lodged upon the pelvic floor there stops, and the stretched perineum is more and more thinned, has less power to turn that part toward the vulval opening, and offers also less resistance to the driving force, and there gives way.

Charpentier attributes great importance in the production of this lesion to exaggerated intensity and irregularity of uterine contraction. He states that in the observations which he has collected, it is always, or almost always, under the influence of an abrupt, energetic contraction of the uterus, aided by a violent and untimely effort of the patient that the rent is produced, and this occurs notwithstanding all attention and precaution which the accoucheur takes to prevent the accident.

In case central rupture of the perineum is recognized in labor, the accoucheur should at once divide the bridge which separates this from the vulval opening, thus permitting the ready exit of the child, and preventing the rent from extending further back to, or through the anus. After delivery, the rent is to be sewed with catgut sutures by the method of Bröse, which was described some months ago in THE NEWS. In case the accoucheur first sees the patient some hours after delivery, catgut sutures are to be used, but the bridge is not to be divided unless union fails; in case of such failure, the bridge should be divided, and the sutures reapplied.

THE ISOLATION OF THE TEMPERATURE SENSE.

THE assumption of the existence of a nervous mechanism for the transmission of thermic stimuli, as contradistinguished from general tactile sensation, cannot as yet be regarded as proven, although many clinical observations apparently speak in its favor. Several cases are on record in which, as a sequence of some more or less pronounced lesion of the central nervous system, there existed cutaneous hyperæsthesia in regard to variations of temperature, while, at the same time, no correlated exaltation of general sensibility was appreciable. Instances have also been noted in which, in a given cutaneous area, complete absence of tactile sensibility was coincident with the retention of partial thermic sensibility.

Such facts do not constitute conclusive evidence. They undoubtedly suggest the existence of distinct channels for the transmission of stimuli, but they also suggest the possibility that in certain diseased conditions the nerves involved may be better able to transmit an impulse of thermic origin than one derived from pressure, or even that a diseased sensory centre may be more receptive to one stimulus than to others.

In a most ingenious series of experiments which were first described in THE MEDICAL NEWS of May 30, 1885, and which have since been widely quoted and accepted, DR. MACKENZIE, of Baltimore, succeeded in demonstrating an apparent isolation of the temperature sense in the mucous membrane of the upper air-passages. Struck by the observations of DRS. MURDOCH and DONALDSON, who found that in cocaine anæsthesia of the cornea and conjunctiva the power of distinguishing heat and cold was retained by these parts, Mackenzie applied the same method of investigation to the mucous membrane of the oropharyngeal cavities and nasal passages. Six persons, hospital patients, were taken for the experiments. Having thoroughly anæsthetized the mucous surfaces of the soft palate, uvula, and nasal passages with a four per cent. solution of cocaine, a probe, which had been previously immersed in a mixture of ice and salt, was made to impinge upon the parts rendered insensible to contact and pain. A distinct sensation of cold was complained of in each instance. The opposite extremity of the same probe was then heated over the burner of a lamp used for laryngoscopic purposes, and in its heated condition carried over the anæsthetized areas. While absolutely no pain was felt by any of those experimented upon, there was a marked unanimity of the answers, given voluntarily, in regard to the sensation of heat. In three of the cases an eschar followed the application of the heated probe, and in one an acute pharyngitis developed; yet at the time of application no pain was felt, though the temperature sense remained intact.

At the first glance, the thesis would seem established. Here was undoubted coexistence of tactile anæsthesia with retained, though diminished, sensibility to thermic stimuli. Closer examination, however, reveals an evident and most probable source of

error. Cocaine gives immunity from pain only to that area of mucous surface to which it is applied, and to the parts immediately subjacent to a depth which, while not definitely determined, is certainly not great. Any increment or decrement of heat effected in the superficial insensitive area by the application of hot or cold metal, will produce corresponding changes in temperature, modified only in degree, in those subjacent parts to which the obtunding influence of the cocaine has not extended, with a resultant mild sensation of heat or cold with absence of pain. It is as though one held, for an instant, a live coal in the gloved hand. Here, too, would be the sensation of warmth without pain.

Before we can accept the assumption of structural differentiation for the reception or transmission of different kinds of neural stimuli, one of two things must be shown, either that there exist specific nervous end organs adapted to such purposes, or that there is some point between periphery and centre at which the destruction of nerve fibres shall produce either anæsthesia of a given cutaneous area with retention of temperature sense, or the direct converse of this condition.

THE CONGRESS CONTROVERSY AND THE CODE.

We are in receipt of the following letter from a subscriber to The News, and, although the questions asked have been fully answered many times in our columns, they are of such importance and still hold such prominence in professional consideration that they demand, at least, a brief reply.

Carterville, Ill., January 19, 1886.

To the Editor of The Medical News.

Dear Sir: What is the real trouble with reference to the International Medical Congress? Does it not have reference to the recognition and participation of the New Code men? If that is not the gist of it, what is?

Is their participation essential to the success of the Congress? Why should they be recognized in an International Medical Congress and not in the American Medical Association — how can you or any one else favor the one and not the other? I am sure these questions are interesting to many of my class.

Country Doctor.

The International Medical Congress is an organization which met first at Paris in 1867, and since, at intervals, in the principal capitals of Europe. It has no constitution and no code of ethics, and its membership is open to all regular physicians who choose to inscribe their names on the register. It is a mass meeting of the profession held for scientific intercommunication, and so broad have been the roads to acquiring membership that at both the London and Copenhagen meetings irregular physicians are known to have inscribed their names on the register, and the fact did not in the least disturb the Committee of Organization, or detract from the success of the meetings. The Congress at Copenhagen accepted the invitation to hold its next meeting at Washington, and the Committee of Organization has no right to demand any test for membership but that which the Congress has sanctioned.

It is one of the unwritten rules of the Congress, from which it has never yet departed, that it will not accept an invitation to meet in a country to which the profession of any other country is unwilling to go, or in which the profession itself is not harmonious. At Copenhagen, when the invitation to meet in America was presented, the question was expressly asked by the President, Professor Panum, if the Code controversy would interfere with the profession cordially uniting to receive the Congress, and the acceptance of the invitation was due to the assurance, by the members of the American Committee, that the Code question would not be raised. The dissensions which were aroused at New Orleans were in direct violation of our national honor, whether rightly or wrongly pledged, and they have caused the disaffection of a large proportion of the members of our profession who are from their eminence the best known abroad. This fact, we are reliably informed, will deter many foreigners, including those who have been the most active participants in past Congresses, from crossing the ocean, since one of the strongest incentives to their coming was to meet those who, as the result of the action at New Orleans, will now be conspicuous by their absence. Hence, a united profession is essential to the success of the Congress.

The American Medical Association can exact any qualification, which it sees fit, for membership in its own body, but it has no power to make laws for, or establish qualifications for membership in the International Medical Congress, and this was finally admitted by the new Committee of the Association at its second meeting in New York last autumn, when it receded from its previous position and decided that New Code men might become members of the Congress, but declared that they should not hold office. So long as the New York members of the American Medical Association meet New Coders in consultation, and in their societies, as they do every day, and coöperate with them as officers of their societies, and as fellow professors in their colleges, upon what logical ground can they object to meeting them on an equal footing in an International Medical Congress? The Congress appointed Dr. A. Jacobi and Dr. N. S. Davis to represent America in its Committee on Collective Investigation of Disease, and they are now acting together and issue circulars over their joint signatures. If these two eminent members of the profession, holding different views on the subject of the Code of Ethics, can serve together on a committee, why not any member, and on any committee, or in the Congress, or in any society which is not

governed by the Code of Ethics of the American Medical Association?

The announcement of the preliminary organization of the Congress, made by the original committee, was received by the profession at large with entire satisfaction and with every indication of cordial and harmonious coöperation. The true gist of the trouble subsequently made, was that a few medical politicians were disappointed at not receiving prominent offices, which were given, as in all previous Congresses, to the most eminent contributors to the advancement of medical science in the country in which the Congress was to meet. At the New Orleans meeting of the Association they, therefore, unexpectedly sowed the seeds of discord. They raised the question of Code and of geographical distribution of the offices, because they knew these would prove plausible motives by which to work upon the feelings of the members and to attain their own selfish ends regardless of the consequences to the profession.

Our National Code of Ethics has proved such a valuable means of consolidating and elevating the profession of our country, that by the sole act of giving it to us the American Medical Association has earned our lasting gratitude. The Code is still the corner-stone of medical progress in this country. We believe that the American Medical Association acts wisely in maintaining adherence to it as an essential qualification for membership in its own body, but its right to impose this qualification upon other societies not in affiliation with it, and, above all, upon an International society, cannot, for one moment, be maintained.

For these reasons we believe that the Code controversy has no right to be dragged into the organization of the Congress, even if it did not threaten to imperil the success of the meeting, or to bring the good name of the American profession into disgrace.

REVIEWS.

A Handbook on the Diseases of the Nervous System. By James Ross, M.D., F.R.C.P., LL.D., Senior Assistant Physician to the Manchester Royal Infirmary, etc. 8vo. pp. 726, with 184 illustrations. Philadelphia: Lea Brothers & Co., 1885.

Dr. Ross is already well known, not only as an able clinical observer, but as the author of the largest and most comprehensive treatise on diseases of the nervous system in any language. This smaller handbook he has specially prepared for publication in America, and is intended for the use of students and for such practitioners whose time will not allow the perusal of large works.

The work is divided into two parts, a general and special neurology, and a good idea of the scope and arrangement may be gathered from a summary of the contents. After an excellent anatomical and physiological introduction, the general morbid anatomy, the symptomatology and principles of treatment are considered. In the special pathology, a clinical classification has been, so far as possible, adopted, and the diseases arranged as follows: affections of the peripheral nerves; disorders of common sensation and of special sense; spasmodic disorders; atrophic paralyses; the spasmodic paralyses; disorders of motor coördination; vascular diseases of the spinal cord; myelitis; diseases of the spinal membranes; certain functional diseases of the nervous system; shock, concussion, and allied conditions; vascular diseases of the brain; encephalitis; atrophy, hypertrophy, and tumors of the brain; aphasia; diseases of the membranes of the brain; paralysis agitans; multiple sclerosis and chorea; and a final chapter upon general diagnosis and cerebral syphilis.

Not every man could have been as successful in the preparation of a text-book after having written an exhaustive work on the same subject, but in this volume Dr. Ross has succeeded in producing a work which will prove as acceptable to the general profession as his large one is to the special student of neurology,

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, January 12, 1886.

The President, Charles McBurney, M.D., in the Chair.

Dr. R. F. Weir presented a patient, thirty-eight years of age, on whom he had performed

TOTAL EXTIRPATION OF THE TONGUE BY KOCHER'S METHOD.

The case was interesting mainly with respect to the rapidity of the healing process. The operation was performed on the 8th of December, 1885, and the patient left the hospital, with the wound healed, on the 5th of January, 1886. He had had, prior to the operation, symptoms of epithelioma involving the right half of the tongue opposite the last molar teeth, for only eight weeks, and during the latter part of this time he had suffered a great deal of pain. The affected portion, about one inch in diameter, was cocainized, and sections were cut off, which gave a negative result under the microscope. To eliminate the possibility of syphilis, the patient was put upon specific treatment, but without effect. After removal of the tongue, sections made deeper in the tissue revealed true epithelioma.

After the side of the mouth had been opened by the incision under the jaw, and the tongue drawn out and split, with the idea that only one-half of it would need removal, it was found that the disease had passed so nearly to the median line, that it would be hazardous to leave any portion of the organ, and, therefore, the entire tongue was removed at the level of the hyoid bone, and the great advantage of the method of operation was thereby fully demonstrated. The patient was fed, as is customary in these cases, every three hours, with rectal enemata, consisting of beef peptonoids two ounces, and whiskey half an ounce. These were continued for twenty-four hours without additional material. The enemata were discontinued on the sixth day. On the second day he was fed by an œsophageal tube.

On the tenth day he could swallow. The tracheal tube was removed on the eighteenth day. The inframaxillary wound was closed on the twenty-sixth day after the operation.

These cases have become comparatively common; but the ability to talk, which this patient retains, was astonishing to the man himself and to those who had seen him.

An important factor in securing success in these cases is the thorough carrying out of the aseptic treatment, which is facilitated by the employment of what is called the sticky gauze, first brought to our notice by Billroth. Dr. Weir had been able, with the assistance of Mr. Marten, the apothecary of the hospital, to prepare a sticky gauze, which he thought superior to that made after Billroth's formula. Billroth's formula is as follows:

Resin	60 gm.
Alcohol (95 per cent.)	1200 "

Dissolve and add

Glycerin	50 "

Impregnate six metres of absorbent gauze, and when half dry rub in

Iodoform	50 gm.

The formula for Dr. Weir's improved gauze is:

Resin	10 parts.
Castor oil	6 "
Alcohol	15 "
Iodoform	5 "

These are mixed together, and applied to the gauze.

OSTEOTOMY OF A CURVED TIBIA WITH OSTEOCLASIS OF THE OPPOSITE SOUND FEMUR, TO OVERCOME A DEFORMITY.

DR. WEIR presented a second patient, a young man nineteen years of age, who entered the New York Hos-

pital on the 29th of September, for the treatment of a deformity of the right tibia. The deformity was due to a disease of infancy, involving the epiphyses, which resulted in a marked curvature inward of the tibia. The arrest of development was such that the tibia itself measured three inches less than its fellow, but the femora were of the same length. There was a corresponding tilting upward of the opposite side of the pelvis, and his locomotion was very awkward. The fibula was of normal length, and was, in consequence, displaced upward and backward. An osteotomy was done on the 3d of October, through the head of the tibia, and the limb straightened, but the result gave only three-fourths of an inch increase in the length. In order to get a more equal length of the limbs, the femur of the sound side was fractured by means of a Colin's osteoclast applied about the middle of the thigh, and the fracture was made transversely. It was with some difficulty that the ends of the fragments could be crowded past each other, but this was finally accomplished after the use of considerable force, and the limbs now are nearly of the same length, there being not more than one inch difference. No diminution in general height occurred.

The progress of the case had been somewhat delayed by the manipulation necessary to keep the limb with the fractured femur in proper position, but the patient is now able to walk very well with the aid of a cane, and is daily progressing.

DR. POORE suggested that fracture produced with an osteoclast is always at right angles with the long axis of the bone.

DR. WEIR thought it possible so to adjust the osteoclast as to secure an oblique fracture, but it did not occur to him that it might be required in this case until the fracture had been made, and the difficulty in overlapping of the fragments had presented itself.

THE PRESIDENT asked whether an oblique fracture could not be accomplished by subcutaneous perforation of the bone in an oblique line.

DR. WEIR thought it altogether probable that such perforation would influence the direction of the fracture, but that simpler methods would suffice.

THE PRESIDENT remarked that the result was admirable, inasmuch as the extraordinary deformity was very perfectly corrected. Dr. Weir's case reminded him of one which presented the opposite result with regard to the length of the limb. It occurred in a man thirty-nine years of age, who, twenty-one years previously, from some injury to the leg, suffered from apparently a diffuse periostitis, and, in consequence, according to the history, he had eleven inches of the tibia removed. Whether this was precisely correct or not, Dr. McBurney was unable to say, but certainly a very large piece was taken away, judging from the present condition of the limb. The patient had used the limb more or less since, with occasional outbreaks of inflammatory swelling, and the escape of small fragments of dead bone. He came to Dr. McBurney with superficial necrosis of the new bony deposit. The entire bone was very much thickened, nearly double the normal width and thickness, and one inch and a half longer than the tibia upon the opposite side. He had not met with a case which showed such a marked increase in the length of that bone. The fibula also seemed to be enlarged. It was difficult to say with reference to that, because the thickening of the tibia was so great that the two bones made nearly a solid column; it was only at the lower portion of the leg that the outline of the fibula could be made out at all.

DR. L. M. YALE recalled a very singular condition existing in a well-known surgeon, formerly of this city, namely, one tibia fully an inch longer than the other. He also wore one boot two sizes larger than the other, and, in sitting, the longer tibia carried the knee up higher than the other, but the femur of that side was correspondingly shorter, and the two limbs were of about the same length. The patient regarded it as an abnormality of development, because he knew of no history of disease to account for it.

DR. C. K. BRIDDON then reported the following

CASE OF NEPHRECTOMY.

Mary Smith, aged thirty-six, native of Ireland, married, was admitted to the Presbyterian Hospital, July 1, 1885. She had enjoyed good health until a few months ago, when she began to suffer from pain in the right side of the abdomen, it was of a continuous character and never paroxysmal; at the same time it was noticed that her urine was turbid, there was no increased frequency in passing it, and there was no hypogastric pain; she was much annoyed by vomiting, headache, and fever. Rest, and the use of emollient cataplasms, sufficed to relieve her for the time, but on resuming her duties in the house the troubles returned.

Physical examination detected nothing of importance in the cavity of the chest.

In the right side of the abdomen was a tumor filling the lumbar region, and reaching to the median line; it had somewhat of the form and configuration of the kidney; it was dull on percussion, the dulness above being continuous with that of the liver; over the lower anterior and inner borders was a line of resonance.

Urine averaged twenty ounces daily, one-half its volume was composed of pus, its specific gravity was 1.018; it was acid and albuminous, but contained no casts.

The diagnosis was pyelonephritis.

July 29.—Tumor has increased in size, it reaches one inch to left of the median line, causes bulging in the lumbar region with some abdominal protrusion; vertically it extends from the tip of the eleventh rib to the anterior superior spine of the ilium; has no acute, but dull continuous pain, and some tenderness on pressure; she has evening exacerbations of temperature, secretion of urine scanty, one-half pus but no casts. The diagnosis was confirmed, the propriety of making an incision in the loin was discussed, favorably entertained, and advised. It was proposed to do a nephrotomy, but preparations were made to substitute nephrectomy if conditions were found to call for it. The patient was prepared by the daily use of baths and the administration of aperients, and the operation was done August 1st with strict adherence to all the details of the antiseptic system, and under the influence of ether.

The lumbar region was made prominent by the use of sand bags, the usual transversely oblique incision was made below the lower border of the last rib, and there was not the slightest trouble in exposing the kidney, which was quite superficial; on opening its capsule, it felt solid, and non-fluctuant, its posterior dimensions were such, that with the index and middle fingers insinuated between the capsule and the gland until the knuckles were in contact with the transverse processes of the vertebræ, it was found impossible to reach the hilum. It was at once determined to remove the organ through an incision in the abdominal walls. After the necessary changes in the position of the patient, an incision about eight inches long was made along the external border of the right rectus muscle. When the peritoneum was reached, a few bleeding points were controlled, and the serous sac was opened; the tumor was at once exposed, its lower part crossed obliquely by the ascending colon, and little else was seen of the intestines, which were kept well within the abdominal cavity by the use of flat sponges.

The peritoneum covering the kidney was next exposed and incised, coming down at once to the capsule, which was opened to about the extent of three inches, this tunic was then separated from the organ, and there was no difficulty in doing so, except at one point on the anterior wall, where it was adherent, and in separating this adhesion the cavity of an abscess was opened. As soon as means were instituted to guard against the entrance of pus into the peritoneum, the cavity was enlarged permitting the escape of about eight ounces of pus; it was entirely emptied, its walls disinfected, and when it was filled with a sponge charged with antiseptic, the operation was proceeded with, the kidney was drawn through the opening in the abdominal walls, and an inspection of its pedicle presented conditions of interest. It was, including the reflected capsule, nearly two inches in diameter. It was not at this stage possible to recognize its different constituents, the only thing that could be distinguished was the presence of a hard body that was believed to represent a calculus. A limited incision was then carried round the pedicle, passing through infiltrated tissue that was probably capsule; a ligature of strong silk was then passed round and secured; it was then transfixed by a second that was secured on either side, and as the size of the pedicle warranted the suspicion that it might shrink so much as to permit hemorrhage, an elastic ligature was applied on the proximal side of the others; the ends of the elastic ligature were cut short, the ends of the others were left long, and they were passed through a drainage tube in the loin; the opening in the posterior wall of the peritoneum was then closed by a continuous suture, shutting off the cavity from which the kidney was removed, from that of the peritoneum, leaving the capsule, stump, ligatures, and drains continuous with the opening in the loin. There was very little exposure of the peritoneum, only that in the immediate vicinity of the operation; its toilet was made as perfectly as possible, and the abdominal wound was closed by three lines of sutures, one for the peritoneum, one for the muscular and aponeurotic structures, and one for the integument. Irrigation was made during the operation with Tiersch's solution, a layer of iodoform gauze was placed over the wounds, the whole supplemented by a dozen layers of mercuric chloride gauze and a quilt of jute.

The patient rallied well after the operation, and was not annoyed by vomiting. At 10 P. M. temperature in the rectum was 101°, pulse 120.

Aug. 2.—Temperature reached 102° in the night; at 9 A. M. it was the same; no vomiting or abdominal pain. Up to 7 A. M. nine ounces of urine were passed; it was albuminous, contained ten per cent. of pus, and hyaline and granular casts. She was ordered only sufficient

morphia to quell pain, and was sustained by nutrient enemata.

3d.—Patient rested fairly well during the night but this morning she has been annoyed by nausea and eructations of biliary matter; there is very slight distention of the abdomen; temperature has fallen one degree, and pulse remains at 120; she has passed seventeen ounces of urine during the past twenty-four hours, it contains but little pus, is acid, specific gravity 1.025, albuminous, and contains hyaline and granular casts. During the day the vomiting became more frequent, coffee colored, or more like porter diluted with water; very slight distention of abdomen, only slight tenderness in the immediate vicinity of the operation wound.

4th.—Condition unimproved, vomiting not relieved by sipping hot water or iced champagne. She was ordered hourly drop doses of creasote; toward noon the temperature went up to 103°, the vomiting ceased after the first dose of creasote, but she went rapidly into collapse, which was not influenced by the prompt use of cardiac stimulants, including the hypodermatic use of camphor dissolved in ether, and she died at 9.30 P. M. seventy-eight hours after the operation.

The kidney removed by the operation was found to be the seat of multiple abscesses; most of these were of considerable dimensions, the largest would have contained an ordinary-sized lemon; they communicated one with another, and through their intercommunication opened by a small orifice into the dilated pelvis; the latter was occupied by an umbrella-shaped calculus weighing 125 grains, and measuring one inch and a quarter by one inch; the nucleus of this was a perfect oval, which had evidently lain transversely across the opening of the ureter, and the expanded portion was formed by accretions around this, forming an incomplete cup for the nucleus, the stem projecting into the ureter; there was a second small oval calculus, and a fragment in one of the abscesses.

When all the cavities had been emptied by expression, and after the organ had shrunken in strong alcohol, it measured vertically six inches, antero-posteriorly four and a half, and transversely three and a half inches.

Autopsy was made on the 5th, about twelve hours after death. It was necessarily incomplete, as it could only be made through the operation wound; the margins of the incision in the abdominal walls were firmly agglutinated; there was no fluid effusion in the cavity of the peritoneum; not a trace of any but conservative processes, save at one point where there was a very insignificant adhesion, between the lower border of the right lobe of the liver and the colon, it was difficult to detect the line of incision in the peritoneum covering the cavity from which the kidney had been removed, so perfect was the process of repair. The stomach was enormously dilated, and filled with fluid similar to that which had been vomited during life. The ureter on the right side was not dilated. The wound in the loin looked well. The stump of the kidney was much reduced in size, and was free from odor—in fact, there appeared to be an entire absence of such conditions as would be likely to cause septic infection.

Report of condition of left kidney by Dr. William H. Porter, Curator. The kidney received for examination was larger than normal and weighed about six ounces (170 grammes); it was pale in color, the capsule a little thickened, and slightly adherent in places to the underlying renal tissue; the surface of the gland, however, after enucleation was fairly smooth.

The cut surface showed both the cortical and pyramidal portions to be enlarged, the former being twice the normal thickness. The markings of the cortical arches were straight, and the parenchyma had a pale granular and fatty look to the unaided eye.

Microscopic Examination.—The epithelial cells, both of the straight and convoluted portions of the uriniferous tubules, showed the protoplasm to be in a state of coarsely granular metamorphosis, which had caused the cells to become swollen and in many places the lumen of the uriniferous tubules was obliterated, while at other places the epithelial corpuscles were becoming necrotic, and detached from the underlying basement substance. At points in the section there was marked evidence of an increase in the intertubular tissue, which in all probability had existed for some time, and was of slow formation and chronic in nature.

The lesion therefore was double, or a chronic diffuse nephritis, upon which a rapidly progressing acute parenchymatous metamorphosis of the epithelial cells had been superinduced.

Remarks.—The first important feature in the history of this case will be found in the absence of such symptoms as are commonly regarded as sufficient to warrant a suspicion of calculus. Pain was not a prominent feature, and was at no time characteristic; there had been some complaint of dull, obscure, fixed, and deep-seated pain in the lumbar region, but at no time was it of a radiating character, and she experienced none of the severe paroxysms which indicate the descent of a calculus from the kidney to the bladder. Of course, it is well known that in exceptional cases there has been an entire absence of such symptoms as could be referred to the kidney. Cases are reported in which large concretions have been found after death, but in which no suspicion of such condition was entertained during life. In very many cases the signs are obscure, in some pointing more to the bladder than to the kidney.

In this case, pain was complained of only a few months before she applied for treatment, and yet the size of the stone would appear to indicate that it had existed long before such symptoms manifested themselves; in fact, the case was looked upon as one of suppurating kidney, and the existence of stone as an exciting cause was scarcely entertained.

The condition of the opposite kidney was a matter for serious consideration. In a paper read before this Society, "On the Causes of Death in Cases of Abdominal Surgery," in October, 1883, a prominent position was given to the influence exercised by inefficient action of the kidneys, on the result of such operations. In the *Annales des Mal. des Org. Génito-urinaires*, No. 5, 1885, is an interesting account of investigations made by Dr. Thiriar, on the condition of the urine after abdominal operations; the result of such observations goes to prove that when the quantity of chlorides in the urine falls below fifteen and a half grains a day, septic peritonitis is threatened.

The amount of urine passed by the patient had been small; there had been no symptoms of obstruction of the urine on the side affected, so we had no opportunity to estimate the condition of the secretion derived from

the opposite side. Catheterism of the ureter was not used, and we had no means of employing the method of Tuschman, concerning which Mr. Morris, in a discussion before the Medical Society of London, is stated to have said "that he was not able to speak of it with confidence." It consists in compression of one ureter by an instrument specially adapted to the purpose. In the absence of such methods of precision, we had to conclude that, from non-existence of tumor on the opposite side, and the absence of toxic symptoms, that the other kidney was in a sufficiently healthy condition to bear the additional tax that might follow the destruction of its feliow.

As stated in the history of the case, the operation was to be explorative in character, the subsequent steps to be determined by conditions found upon making a preliminary incision in the loin. It might have been possible then to have aspirated suppurative foci, but the posterior half of the organ was so apparently solid that the determination of fluctuation was not sufficiently marked to suggest the use of the needle. It might also have been possible to detect a calculus by acupuncture; but I thought that, inasmuch as I could not feel the pelvis with the whole length of the finger buried in the wound, that puncture would be useless. This subject of the selection of the proper operation has occupied the minds of those engaged in this department of surgery, and expressions of opinion have been various, but I think that the very able, and exhaustive analysis made from the reports of a large number of cases by Dr. Samuel W. Gross, and published in the *American Journal of the Medical Sciences*, for July, 1885, has settled the question, and I quote with pleasure the following extract from that portion of the article which refers to the suppurative conditions.

"It will thus be seen, that of 73 nephrectomies for suppurative lesions from all causes, 41 recovered, and 32, or 43.97 per cent., died. Of 93 nephrotomies, on the other hand, 71 recovered, and 22, or 23.65 per cent., died. It, moreover, appears that of 12 nephrectomies after a previous nephrotomy, only 1, or 9.33 per cent., succumbed, while of 61 nephrectomies without preliminary incision and drainage, 31, or 50.81 per cent., perished. In other words, the mortality of removal of the kidney for suppurative conditions is nearly twice as great as after nephrotomy, and a preliminary nephrotomy diminishes the risks of nephrectomy by 41.48 per cent. Hence we may conclude that a suppurating kidney should never be excised until after the failure of nephrotomy, the only inconvenience of which is that a permanent sinus or urinary fistula remains in 29.57 per cent. of the recoveries, either of which may, however, should it prove a source of discomfort, be remedied by subsequent lumbar extirpation of the shrunken sac, with the risk of only 9.33 per cent. In favor of a preliminary nephrotomy, it is also to be declared that it enables us to determine with almost a certainty the condition of the opposite organ, that is to say, if, after a few days of drainage, pus ceases to appear in the urine, the probability is that the other kidney is sound."

With a full knowledge and appreciation of these conclusions, it may be asked, Why was not the kidney incised in the present case, and why was the abdominal substituted for the lumbar section? In answer to the first question, it must be stated that the pathological conditions were not recognized in the loin operation; and in answer to the second, I must express the opinion, that I think it would have been impracticable to remove so large a tumor through the first incision, which was obliquely transverse, and which I prefer to the vertical incision, so ably advocated by Dr. Lange, in an article on "The Surgical Anatomy of the Kidney," published in the *Annals of Surgery*, 1885, an incision which suffices admirably for the exploration of the pelvis, and for the removal of calculi from moderate-sized kidneys, but which, for the removal of a large kidney would necessitate such extension upward as would trench on the domain of the pleura, especially in the not uncommon cases where the last rib is rudimentary, and in which cases the pleura is prolonged outward to the lower border of the eleventh rib. The oblique incision may easily be supplemented by a short vertical, or its terminal end may be prolonged into a V.

I think there are decided advantages in making an opening in the loin for drainage in cases where the abdominal section is determined upon. It only slightly complicates the operation, and permits of perfect closure of the peritoneum with efficient outlet for discharge, and an equally efficient inlet for antiseptic irrigation when it may be required.

The impetus given to the surgery of the kidney by the successful interference in cases of calculus, and the intelligent observation and interpretation of conditions that occasionally follow such operations, has led to achievements which I think may be truly regarded as triumphs in the practice of our art. I refer to the case which recently occurred in Guy's Hospital, in which McClement Lucas removed a hydronephrotic and calculous kidney, and in which case, after a complete recovery, the patient began to suffer pain in the opposite organ, rapidly followed by suppression and uræmic intoxication. Mr. Lucas cut down on the kidney, removing a calculus from the pelvis, which was followed by a free discharge of urine, and recovery. Very similar was the case reported at the last meeting of this Society, in which Dr. Lange had done a nephrectomy, which some time after was followed by symptoms of acute anuria, and in which an exploration of the pelvis of the remaining kidney enabled the operator to remove an obstruction from the ureter, and thus saved his patient from impending dissolution.

DR. POST presented a photograph he had lately received, and which represented the present condition of a patient on whom he had operated for

EPITHELIOMA OF THE LOWER LIP

one year ago. The disease was extensive, and involved a little more than the left half of the vermilion border of the lip, and extended into the cheek a short distance beyond the angle of the mouth. The two lips appeared very nearly equal.

The operation was performed as follows:

A horizontal incision was made from the left angle of the mouth to a point beyond the morbid growth, and a vertical incision was extended downward from the left extremity of the horizontal incision. Another vertical incision was made on the right side of the median line, and the two vertical incisions were joined by a second horizontal incision below the level of the disease, and the tumor was thus removed. The two horizontal in-

cisions were extended to the left so as to include a large flap which was drawn to the right so as to meet the remaining portion of the lip on that side. The upper margin of the transplanted flap was provided with a vermilion border by stitching the mucous membrane to the skin. To prevent the puckering of the integument, and to give symmetry to the two lips, a triangular portion of the cheek was removed, the base of the triangle being on a line extending from the left angle of the mouth outward into the cheek to the extent of two centimetres, and the apex being at a point two and a half centimetres above the base. The parts were secured in apposition by pin sutures and fine silk. The operation was a modification of Burow's.

THE PRESIDENT said it had seemed to him that in similar operations for restoring the lower lip it is only necessary to remove the thickness of the skin, not even including the muscular tissue. If the skin alone is removed, the flap will fit, the muscular substance will contract, and the mucous membrane will take care of itself.

DR. POST said that he retained only such an amount of mucous membrane as was necessary to restore the vermilion border of the lip, and the result had been to make the two lips almost symmetrical.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Annual Meeting, January 18, 1886.

THE PRESIDENT, C. A. LEALE, M.D., IN THE CHAIR.

DR. LAWRENCE J. MCNAMARA, Instructor at the Carnegie Laboratory, read a paper entitled

A STUDY OF THE ETIOLOGY OF TUMORS.

It was intended, he said, as an examination of some of the existing theories on the subject, and an attempt to adapt them to the various forms of tumors, which he had personally investigated. The existence in the body of an independent growth, distinct in its histological elements from the surrounding matter, drawing nutriment from the general system, and liable at certain periods of development to infect the organism, has always been a perplexing, though fascinating subject to the observer. Advances in histological work have enabled us to make a partial classification of these new growths, according as they are formed on some type of existing normal tissue, as epithelial, muscular, nervous, or connective tissue. This group of neoplasms, under which are ranked tubercle, syphilis, glanders, etc., has a distinct place as formations of an infectious origin; and are no longer considered as tumors similar to those now under discussion.

The class of tumors formed after types of normal tissue which are most frequently brought to the notice of the surgeon are sarcoma and carcinoma. These are distinguished from tumors of a benign character, by secondary formations or metastases, and the tendency to recur when removed. These metastatic or secondary deposits bear the same relation to the structures in which they have found a resting-place as did the parent tumor. They assume the changes in growth, development, and invasion of organs identical with the primary growth. The channels of infection are the lymph and blood. In the ordinary cases of carcinoma, examination of the advancing mass shows infiltration of the normal tissue by epithelial cells. The lymphatics are found plugged with epithelial elements, and the glands contain the same distinct cells. In this formation, at least, it is unnecessary to imagine a virus, transmitted to the body from without, as the cause of the proliferation.

There can be no doubt of the malignancy of cancers. The metastases, however, are always of epithelial formation, similar to the primary cancer, and the epithelial cells resemble one another in shape and appearance. The important fact lies in the misplaced epithelial cell. Like the forms of vegetable life, the cell is influenced in its activity by the nutriment which surrounds it; and a modification of this condition leads to a change in its activity. The epithelial cell, if placed in a tissue receiving more nutriment than its own, must, undoubtedly, show some changes in its activity. The transplanting of the spur to the comb of a cock is a familiar example. In some cases of cancer of the breast it seemed to him that he could make out a distinct connection between the swollen epithelium of the duct and the cells beyond, and this fact has been mentioned by others. The epithelium in the connective tissue and the duct seemed identical in form and appearance.

The diagnosis of cancer cannot be made until the epithelial cells form nests in the connective tissue. If this epithelial element does not come from the proliferating interpapillary processes, it may have existed previously; and to suppose this is to admit the embryonic theory of Cohnheim. The arguments advanced by its originator offer very convincing proof of the etiology of many complex tumors, like the sacral teratomata, the mixed tumors of the parotid, dermoid cysts, etc. Applied to the sarcomatous group of tumors, the theory has no direct proof of their embryonic origin. There cannot be as much reason for accepting the belief that epitheliomata of the lips, pylorus, or rectum, originated from an embryonic epithelial cell displaced and started in growth by continued irritation, as believing that irritants may cause the invasion of the connective tissue by the proliferated epithelial elements.

In sarcomatous growths, however, more difficulty is experienced in accepting this embryonic theory. Until proof can be furnished that these embryonic cells exist in the body and develop into a distinct tumor under favorable circumstances, the theory of Cohnheim cannot be logically entertained. The transplanting of embryonic cartilage to the adult animal, and its development into a tumor, proved, he thought, the fact of the power of embryonic cells to live and multiply in a mature matrix. It is conclusive, however, that the embryonic cells will grow in the mature organism under favorable conditions. Another difficulty in determining the embryonic foci is the similarity under the microscope of embryonic cells, the round cell of inflammation, and the small cell of sarcoma.

Having quoted from Billroth in the summary of his remarks on the etiology of tumors, Dr. McNamara remarked that the perplexing theory of predisposition as the cause of tumors is found in many of the theories; and said that it serves the purpose of hiding their defects and increasing the obscurity in which the cause of these neoplasms lies. Malignant growths have often been compared to the infective granulomata in their course and development. The changes which occur in these infective neoplasms, such as necrosis and the like, may find

counterparts in the malignant deposits of tumors. Clinically, there are other points of resemblance; but the infective granuloma, besides possessing the power of invasion of tissues, may be inoculated. Clinical efforts or experimental works have not been able thus far to connect a bacterium with the cause of tumors.

Still, the infectious origin of sarcoma possesses at present great attractions. The discovery of a vegetable growth as the cause of actinomycosis has some bearing on this subject; and actinomycotic tumors were called, before their parasitic nature was proved, osteo-sarcoma, tuberculous tongue, etc. Sarcoma, when rapidly growing, presents changes of a similar character in the reactive appearance of the cells. If this variety of tumor is caused by a microörganism, it must be of a nature which requires very favorable conditions for its development.

If a microörganism be considered as the cause of carcinoma, the question why it should affect the epithelial cells alone, does not seem capable of explanation. Microörganisms cannot produce an epithelial or connective tissue cell; since one being cannot form another higher in the animal economy than itself. The action of the microörganism is of an inflammatory character, specific in its nature. In carcinoma the inflammatory changes represent the action of the cellular matrix. The same may be said of sarcoma. The hyperplasia of the matrix is but an indication of the efforts of the tissue to cast out or destroy the foreign body. In conclusion, he remarked that it seems that to no one theory can be assigned the production of these tumor-growths.

DR. J. W. S. GOULEY thought that Dr. McNamara's position concerning the question of microörganisms was well taken, and said it was his belief also that it is not likely that a microörganism can end in an epithelial or any other kind of cell. The cell itself is sufficient to give rise to the mischief which is excited in cases of advanced cancer.

THE PRESIDENT remarked that the author of the paper had, with a single sharp stroke, thrown aside the theory of Darwin, when he stated that one being could not form another higher in the animal economy than itself. He then related a case in which he removed a schirrus of the breast, where three of the patient's sisters died of cancer. The family history showed that the father, who was a resident of Richmond, Va., had died of a "tumor of the stomach," the exact nature of which could not be ascertained, and that the mother had died of a "tumor of the liver." In this patient the cancer did not return in the breast, but three years after the removal of the mammary growth she died of metastatic cancer of the liver; the lungs being also finally implicated. One sister had cauliflower cancer of the uterus, and another schirrus of the uterus. It was a curious fact, that the trained nurse who attended the lady whose breast he removed also had mammary cancer. One year afterward he removed this also, and a year after that, the axillary glands. It would be of interest, he thought, to know whether it was possible that there could have been a transmission of the affection from one individual to another in these cases.

DR. DANIEL BROWN related a case which he thought might serve to throw some light on the etiology of tumors. A young lady twenty-two years of age, residing in Eastern Pennsylvania, fell on a doorstep and slightly bruised her hip. Afterward no further effects were noticed for some sixteen or eighteen months, when she began to suffer considerable pain in the part. It was at first supposed that she had rheumatism; but afterward a diagnosis of hip-joint disease was made, and a blister was applied. In a few weeks she became unable to walk, and now a small tumor made its appearance over the head of the femur. This growth gradually increased in size, and it was found to be an osteo-sarcoma. The patient was brought to New York and placed under Dr. Brown's care, and at this time the tumor measured twenty-eight inches in its longest diameter, occupying the whole of the ilium, together with the upper fourth of the femur. The late Dr. James R. Wood saw the case in consultation with Dr. Brown; but it was thought best not to perform an operation. The patient finally died, and the growth was found to weigh between forty and fifty pounds. The chief interest of the case lays in the apparent development of this enormous tumor from so slight a cause.

DR. MCNAMARA said that the occurrence of several cases of cancer in one family, as mentioned by Dr. Leale, might be due to predisposing causes, such as climatic influences, etc., to which they were all equally exposed.

DR. FRANK GRAVES presented some interesting pathological specimens for Dr. Janeway, who was unexpectedly prevented from being present. The first case was one of

EPITHELIOMA OF THE ŒSOPHAGUS,

in which there resulted a stricture of the latter four inches in length. Both recurrent nerves were involved, and during life there was paralysis of both vocal cords; neither abduction nor adduction being well performed. Another interesting feature of the case was that the first symptoms appeared after the patient had swallowed a piece of bone, which he supposed had become lodged. Tracheotomy was performed by one of the house physicians of Bellevue Hospital, in order to avert impending suffocation from the laryngeal symptoms. He died as the result of exhaustion, as he was unable to swallow food, and had great distress in respiration. At the autopsy there was found dissemination of the cancer in the liver, lungs, and bronchial glands. The main point of interest in connection with the case was, from the comparative rarity of the circumstance, the implication of both recurrent nerves by the pressure of the growth.

The second case, the specimens from which were presented, was one of

PRIMARY TUBERCULOSIS OF THE KIDNEY.

There was pyonephritis, and the right ureter was obstructed. The inflammatory process had extended from the kidney to the bladder, which was found in a condition of tubercular cystitis.

DR. GOULEY inquired whether there was any history in the latter case.

DR. GRAVES replied that there was not; the patient having been brought into the hospital *in extremis*. Very few tubercles were found in the lungs, and he thought that there could be no doubt that it was a case of primary tuberculosis of the kidney.

DR. GOULEY thought that the question might be raised whether the tubercular trouble did not commence in the bladder, rather than the kidney. In at least two cases of his own, both of which terminated fatally, such was the case; and in one or two others the tubercle commenced in the urethra. One of his cases he had the opportunity of following up for a year. It commenced apparently with a mild cystitis, and this gradually became more aggravated, until the ureter and kidney were involved. The tubercular character of the trouble was not, however, at first suspected.

DR. GRAVES said, in reply, that in this case the trouble in the bladder was clearly secondary to that in the kidney, since, in the latter, the disease was much further advanced than in the bladder; while the ureter was open at its lower extremity, where it enters the bladder, but above, toward the kidney, it was occluded.

ELECTION OF OFFICERS.

The annual election of officers resulted as follows:

President.—Dr. Charles A. Leale.

Vice-President.—Dr. John Shrady.

Recording Secretary.—Dr. P. Brynberg Porter.

Corresponding and Statistical Secretary.—Dr. Glover B. Arnold.

Treasurer.—Dr. E. S. F. Arnold.

Members of the Executive Committee.—Drs. John H. Hunter and C. S. Wood.

After the meeting there was a collation and social reunion in the Library of the New York State Medical Association in the Carnegie Laboratory.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, January 7, 1886.

THE PRESIDENT, B. F. BAER, M.D., IN THE CHAIR.

DR. HOWARD A. KELLY exhibited recent specimens of

PYOSALPINX, HYDROSALPINX, AND PAPILLOMA OF THE HILUM,

with gelatinoid thickening of the Fallopian tube. The histories of the cases will be given at some future time.

DR. GOODELL stated that while he recognizes the necessity for operation in pyosalpinx, he does not think it necessary in hydrosalpinx. He now refuses to operate in some cases of cystic disease in which one ovary may contain a cyst as large an an orange, or in which the tube may be distended to the size of a sausage, when the sufferings of the patient and her general symptoms are not severe enough to warrant the operation. In many of these cases the symptoms may all be removed by the rest treatment, and it should first be tried. Small cysts are frequently found in ovaries, especially when fibroids are present, but they do not necessarily develop into large ones. In many cases the cause of pelvic symptoms can be diagnosticated by exclusion only, and even when small cysts or dilated tubes can be felt, treatment should be first tried and will be sometimes successful without operation. He thinks the error of the present time is in the direction of too much surgical interference.

DR. MONTGOMERY remarked that there is a class of cases suffering from small ovarian cysts or distended tubes, in which the rest treatment or any other loss of time could not be thought of, and in which operation seemed imperative. This is on account of the pecuniary condition of the patient, who may be self-supporting, or may be the only support of others. The suffering and exhaustion of the disease incapacitating them from work, relief is imperatively demanded, and he considered operation justified.

DR. GOODELL recognized this element of poverty, and has operated for this reason in some instances. He was led to make his remarks by a case now under his care. A lady was sent to him for operation after an opinion had been given by an experienced gynecologist of another city, that relief could be attained by operation only. On one side the ovary was enlarged and the other ovary was prolapsed and tender. Rest treatment had wholly cured her. In these remarks, he meant to cast no reflection on any of Dr. Kelly's cases. Pus was present in all of them, and operation seemed to be demanded in all.

DR. BAER had been strongly impressed lately with the views expressed by Dr. Goodell. Dr. Baer thought all conservative means should be tried before operating.

DR. KELLY replied that he had presented the specimens purely from an anatomical and pathological standpoint, and that he will give the histories at some future time, when the results of operation are well demonstrated. In each of them operation was imperatively demanded to save life. It is in such cases as those presented this evening that the great work in the future must largely lie. If the details of ovariotomy have been perfected, in such cases as these the chapter is only being opened. They are not examples of Battey's operation or Tait's operation, but stand as representatives of classes of disease well defined with equally well-defined indications for treatment. The extraordinary difficulty of digging such masses as these out of the pelvis makes operative interference very fatal, although it is the only resort.

DR. WM. GOODELL read a paper on

A YEAR'S WORK IN LAPAROTOMY.

(See page 117.)

DR. MONTGOMERY thought Dr. Goodell should be congratulated upon his success, which is remarkable for operations in unselected cases in the United States. He thought the knowledge of the safety attending the application of Monsel's solution to oozing abdominal surfaces very gratifying. He would have used it recently, but for the fear of bad after-effects. He must, however, again enter his plea for the second ovary. In young women small ovarian cysts are common; they are frequently found in post-mortem examinations when there had not been the slightest evidence during life of their presence; and evidently these small cysts do not necessarily develop into large ones. The two cases of secondary ovariotomy reported by Dr. Goodell, are not sufficient to warrant the rule of removing the second ovary when it is but slightly diseased. As a counter weight to Dr. Goodell's cases, he would mention that in the instance of a young married woman from whom he removed an ovarian tumor, and in which he left the other ovary, which was slightly affected, pregnancy has since occurred, followed by the delivery of a living child.

DR. KELLY remarked that Dr. Keith had had remarkably good results from the application to oozing surfaces

of a solution of pernitrate of iron. He has observed the gradual disuse of carbolic acid in washing waters in operations. Dr. Kelly prefers boiled or distilled water as used abroad, as he is sure that carbolic acid and other germicides are frequent causes of poisoning, and bad results after the operation. He asked Dr. Goodell what were his rules respecting the use of the drainage tube.

Dr. Baer had experimented with Monsel's solution. In one case in which he used it, he attributed the fatal result to it. The coagulation by the iron is unsightly, and he should now consider it a last resort. He had had very good results from pressure by packing sponges against the bleeding points combined with external pressure. He withdraws the sponges at the last moment before tightening the sutures, and then bandages the abdomen tightly.

Dr. Goodell remarked that Dr. Montgomery was perfectly right in his defence of the second ovary, and he himself had performed double ovariotomy in only seventeen cases of the twenty-eight. He did not believe that every ovary studded with cysts would inevitably degenerate into an ovarian tumor. So in the case of slightly diseased ovaries in young married women he would be disposed either to let them alone or to remove the diseased portion only. But in women approaching the climacteric, or where other conditions make it advisable, he would remove the second ovary as useless in itself, and as a possible source of future trouble. He had used the drainage tube but three times during the past year: once in the unfinished case of oöphrectomy, again in the case of torn bladder, and in the case requiring over thirty ligatures, and with universal adhesions. In general, he uses it when a free oozing of blood is to be expected, but he regards it as a source of trouble, and removes it as soon as possible.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 21, 1886.

The President, A. Jacobi, M.D., in the Chair.

REFLEX SYMPTOMS IN NASAL AFFECTIONS.

Dr. E. Gruening, of the Section on Ophthalmology, opened a discussion on this subject.

He said that, in his remarks, he would exclude ocular affections resulting from extension of catarrhal processes from the Schneiderian membrane. Having mentioned that hemicrania and asthma have been cured in a considerable number of instances by the removal of sources of irritation in the nasal passages, as reported now by many observers, he remarked that to the ophthalmologist the reflex apparatus of the nose is of very great interest. The connection between the latter and the eye is intimate, and the relations of the two are reciprocal. Thus, irritation of the nasal mucous membrane frequently produces lachrymation and other eye symptoms; and in the case of certain irritable eyes, exposure of the organ to a strong light brings on attacks of sneezing. Knowing that ocular symptoms are met with in connection with nasal affections, we may reason, *à priori*, if there is no other apparent cause, that the former are dependent on the latter; and if, after appropriate local treatment, the eye-symptoms still persist, we may conclude, *à posteriori*, that such is the case.

In simple cases the instillation of cocaine into the nostrils often affords a satisfactory test as to whether the ocular trouble is dependent on nasal irritation or not; for if it affords relief to the eye symptoms, we may conclude that the latter are to be attributed to the condition present in the nose. Dr. Gruening then related several cases of his own, as examples in which the eyes were affected for many years in consequence of comparatively mild affections of the nasal mucous membrane, and in spite of the most persevering and skilful treatment, directed to the ocular condition; but in which the eye trouble promptly disappeared as soon as the nasal affection was removed by appropriate treatment.

All the cases, however, were not of this simple class, and he then related several in which the reflex eye symptoms were due to more serious pathological conditions of the nasal cavities. In them also the eye trouble disappeared as soon as the source of irritation in the nose was removed. In one instance where the patient had suffered for many years, the eyes were permanently cured on the very day that a large mass of hypertrophied tissue was removed from the nose. During the past two years he said he had met with some two hundred cases in which he could refer the ocular symptoms to nasal trouble; but the treatment, which varied according to the circumstances of the case, was not always successful. In most of the unsuccessful cases, however, the patients had disappeared before the treatment was completed, or perhaps was fairly commenced. Still, in about one hundred and fifty of the two hundred cases complete relief had been afforded by the removal of abnormal conditions of the nasal passages.

Among the symptoms mentioned as most frequent in these cases of reflex eye trouble are: Burning and smarting sensations in the eyes, more pronounced in the morning; inability to fix an object in ordinary daylight; irritation and gluing together of the lids; extreme sensitiveness to cold and wind; lachrymation. Other characteristics were; inefficiency of ocular treatment, and inefficiency of nasal treatment, even in spite of the absence of nasal symptoms.

Dr. Thomas E. McBride related five cases which he thought served well to illustrate the general subject under discussion. The first was that of a gentleman who consulted him in 1882 for well-marked migraine. The attacks were thoroughly characteristic and lasted for about eighteen hours, leaving him completely exhausted. In addition to appropriate hygienic and dietetic measures, he placed the patient on the use of arsenic and extract of cannabis indica. The former he gave up in about six weeks, but the latter he continued, in increasing doses, for fourteen months. By this time the seizures were less frequent than formerly, but the patient had become disgusted with the cannabis indica, and complained that it made him sick. Indeed, he had suffered from almost constant nausea. In consequence, this remedy was withdrawn, and he was placed on the use of bromide of sodium, under which the attacks of migraine became still less frequent. While in Europe, however, he chanced to come into the hands of Hach, who discovered that he had post-nasal catarrh; and the successful treatment of this completely and permanently cured the migraine.

The second case was that of a boy of eleven years of age, of neurotic family history, who for several years

had suffered greatly from headache, which was always much worse in winter than in summer. It was frontal in character; and it having been discovered that he had nasal catarrh, he was placed under treatment for this, and afterward had no more headache.

The third case was that of an unmarried lady, also of neurotic antecedents, who was affected with lithæmia, and suffered from neuralgia and headache. The latter was situated in the upper part of the forehead, and extended toward the vertex. She was referred to Dr. Lefferts, who found that she had hypertrophy of the mucous membrane of the inferior turbinated bones; and the appropriate treatment of this condition put an end to her headache and neuralgia.

The fourth case was that of a married lady of fifty in whom the menopause had occurred at the age of forty. She suffered from hemicrania and hay fever; but was cured by the local treatment of the nasal mucous membrane by a rhinoscopist.

The fifth case was that of a married lady who suffered from difficulty of deglutition and the regurgitation of food into the mouth after it had been swallowed. Four years ago she was treated in Europe for post-nasal catarrh, which is still not entirely relieved. Gastric catarrh also was undoubtedly present. Dr. McBride placed her on the use of iron and arsenic, and applied to the nasal mucous membrane a spray of four per cent. solution of cocaine, with the effect of completely relieving the symptoms mentioned; and thus far there has been no return.

DR. BEVERLEY ROBINSON called attention to the fact that nasal disease might produce reflex affections of the respiratory and digestive tracts, the genito-urinary apparatus, and the cutaneous surface. On the present occasion, however, he said that he would limit his remarks to hay fever and asthma. It was time, he thought, that the designation hay fever was given up, and that the affection thus called should be given its true name, vasomotor coryza, as proposed by Dr. John N. McKenzie, of Baltimore. It is a curious fact, however, that the old pollen theory has recently been again brought into prominence by the advocacy of no less distinguished an authority than Morrell Mackenzie, of London; thought it is no longer accepted by the great mass of observers. Still, pollen undoubtedly acts as an irritant in certain cases. Dr. Robinson then gave a sketch of the researches of Beard, who tried to prove that hay fever is purely a nervous affection, and of Daly, of Pittsburg, who, five years later, showed its dependence on local conditions in the nasal cavities. Since then, much light has been thrown on the subject by Roe, Sajous, Bosworth, and John N. McKenzie. The nasal trouble present in any case may be either permanent or temporary.

Sometimes cough is dependent on nasal conditions —as, for instance, the presence of a polypus, deviated septum, atrophy, hypertrophy, and chronic rhinitis; but, although asthma sometimes occurs in connection with these conditions, they may, of course, exist without giving rise to asthma. In this connection, he related the case of a well-known physician of a neighboring city, who suffered greatly from the latter affection. A number of polypi were removed from his nose; but the asthma, which was no doubt dependent on an old bronchial catarrh, still remained. We must not forget, also, that asthmatic symptoms may be the result of reflex influence from abnormal conditions of other organs, such as the liver, stomach, uterus, and even, according to some observers, the spleen. In every case of asthma it is necessary to make a thorough investigation of the cause.

In regard to the nasal mucous membrane, Dr. Robinson said that in all probability there are areas of special sensibility at times, but his own observations went to show that these are not constant. The sensibility is probably less circumscribed and more general than has been supposed. Apart from any nasal trouble, there must be a special personal tendency, since there are many cases of nasal disease without any resulting reflex conditions.

Cocaine has been recommended as of special service in making the diagnosis of nasal affections, on account, first, of its anæsthetic properties, and, second, because it diminishes the congestion of the parts. He was convinced, however, that cocaine is not always a successful anæsthetic, especially after it has been used for some time; and that, while its primary effect is to diminish the vascular supply, its subsequent action is to increase this. In the treatment, we must be guided by the condition present, and it is well to remember that nasal hypertrophy does not always exist. Dr. Robinson spoke particularly of the good effects of carbolic acid in the treatment of nasal disease.

DR. GOODWILLIE exhibited several wax casts of nasal obstructions in which he had operated. One was a case of deviated septum, with exostosis and hypertrophy of the mucous membrane; in another, there was complete occlusion of the right nostril; and, in another, in which the patient was a sufferer from hay fever, there was hypertrophy of the inferior turbinated bones, with dilatation of the pharyngeal orifice of the Eustachian tube. In concluding his remarks, he said that the sickness often complained of in these cases of nasal disease is generally produced by the fetid secretions which get into the stomach, causing nausea and interfering with digestion.

DR. SIMON BARUCH thought that this whole subject is entirely too much neglected by the general practitioner; and yet it is one which concerns him almost as much as the specialist, since, in a large number of these cases, there is no very well-defined nasal trouble. Since the publication of Hach's treatise, he has investigated the matter to a considerable extent, having secured a dispensary appointment for the special purpose of obtaining the opportunity of making rhinoscopic examinations, and learning how to treat nasal difficulties. He, therefore, availed himself of this occasion to relate briefly six cases in which various reflex symptoms were overcome by nasal treatment. One was a case of reflex cough, two were cases of headache occurring in young girls, one was a case of asthma, and one was a case of severe pain in the right side of the throat, associated with excessive sneezing. In the latter instance he found enlargement of the lower turbinated bone of the right side, and other nasal troubles, and the treatment adopted was that of the galvanocautery. He has also had a number of unsuccessful cases; but to these he did not refer particularly.

He regretted that in the discussion nothing had been said in regard to the examination and treatment of this

class of cases, as it is highly desirable, he thought, that general practitioners should be able to recognize and treat them before they get so bad that it is necessary to send them to a specialist. One of the most frequent conditions present is hypertrophy of the turbinated bones, and in his own experience he has usually found that this is easy to recognize; while the application of the galvano-cautery, if a good battery is employed, is an easy and efficient method of treatment.

Dr. Henry Schweig said that he must take exception to the last remark of the previous speaker. He believed that there is no procedure which requires more care and judgment on the part of the operator than the use of the galvanocautery; so that, as a rule, only an experienced specialist is capable of properly applying it. While its judicious employment is very efficient, he felt convinced that the abuse of this method of treatment is much more frequent than its intelligent use. In order to accomplish the desired end, we should destroy the cavernous tissue without injuring the secreting surface of the nasal cavity, and the application should always be made from within outward, instead of the reverse. Unless care is used, great and permanent harm may result to the patient; and one very common error is to use too great heat; a dull red heat being all that is required.

The President said he would take this opportunity to make some observations in regard to a point to which attention has never been called, so far as he is aware. For a considerable number of years he has noted the influence of catarrh, hypertrophy, and other changes in the nasopharyngeal cavity upon parts of the nervous system, which had not been alluded to in the present discussion. In a large number of children there are found what are known as peculiar bad habits, such as winking, frowning, drawing up the nose, twitching of the face, and shrugging of the shoulders. He has ascertained, however, that frequently these nervous phenomena are not due to bad habits at all; and thought, therefore, that every so-called bad habit should be investigated, for the purpose of finding out its origin. These cases are not always simple. What is at first a local chorea minor sometimes eventually results in a general chorea minor. Some twelve years since his attention had been called, by a work published in Bremen, to the fact that hemicrania is sometimes dependent on chronic pharyngitis and amygdalitis; and since then he had some hundreds of cases in which this local chorea was associated with conjunctivitis, rhinitis, pharyngitis, enlarged tonsils. In every case of local chorea he had found chronic nasal catarrh and chronic pharyngitis, and he had never found the nasal trouble without the pharyngitis. In many instances it was difficult to determine which of the two had been the original affection.

It is well known, he went on to say, that what is known as the third, or pharyngeal tonsil, in the back of the fauces, is frequently the cause of inter-pharyngeal abscess; but he believed that inflammation and enlargement of this pharyngeal tonsil are also common causes of chronic pharyngitis and chronic rhinitis. They also occasion migraine and hemicrania, and it is evident, therefore, that the whole nasopharyngeal mucous membrane is capable of giving rise to these reflex nervous symptoms. It is a point of practical importance to know that very often the treatment of only one small spot is all that is required.

BALTIMORE GYNECOLOGICAL AND OBSTETRICAL SOCIETY.

Stated Meeting, January 12, 1886.

The President, George W. Miltenberger, M.D., in the Chair.

Dr. L. E. Neale read a paper entitled

TWO CASES OF DYSTOCIA,

of which the following is an abstract.

Case I.—A white primipara, æt. twenty-five years, in labor at term with living child, presenting L. S. I. A., breech movable above superior strait, and unaccompanied by inferior extremities. Descent failing, the attending accoucheur resorted to chloroform, manual extraction, and Elliot's forceps, with an unsuccessful result. Another physician also tried, with the patient under chloroform, (a) manual extraction, (b) to pull down a foot. Dr. Neale was called in consultation and after many trials, including the use of Tarnier's forceps, which slipped, finally succeeded in bringing down a foot and extracting an asphyxiated child which was restored by Schultze's method. Mother well.

Dr. Neale called attention to the use of (1) Barnes's method of decomposition; (2) the obstetric forceps in such cases of difficult, *frank* (Pinard) breech labors. He referred to Tarnier's explanation of the cause of difficulty in engagement and disengagement being due to the legs *splinting* the trunk, and thus preventing flexion of the same; and he thought that this fact might indicate the propriety of Barnes's plan of treatment. He cited several authorities, and agreed with those who considered this method difficult, if not dangerous, when the breech occupied the pelvic cavity, and he was of the opinion that manual extraction directly upon the breech should not be utterly ignored. Most recent authorities sanctioned the use of the forceps in *frank* breech cases, Ollivier declaring that the instrument may be applied to the breech even at the pelvic brim. Lusk particularly recommended the Tarnier forceps; and Dr. Neale thought the instrument should be tried before resorting to more dangerous instrumental measures.

Case II. was one of contracted pelvis occurring in an Irish woman, thirty years of age, in labor at term with third child. Her two former labors were terminated by forceps operation, the child dying on each occasion; and in this, her third labor, with child presenting vertex R. O. I. P., head movable at brim, forceps and version both repeatedly failed, and the child here also died during the accouchement. Dr. Neale was then called in consultation, and with great difficulty succeeded in delivering by craniotomy a ten-pound child. The puerperium was normal. The external pelvic measurements were normal; the internal conjugate was about 2¾ inches; the symphysis pubis was about 2½ inches long, and had an exaggerated inclination, and there was, moreover, a marked thickening of the pelvic bones. The entire build of the woman was short, stout, massive, and powerfully muscular, and there was no sign or history of rachitis. Dr. Neale preferred version, when

practicable, to high forceps in contracted pelves not less than 2¾ inches in smallest diameter, and he cited authority in support of this view. In such cases as labor at term with living child, he would at once resort to version, if practicable; if impracticable, to high forceps, cautiously; and, failing in this, to craniotomy. With dead child, presenting head at the brim, to craniotomy at once. If such cases be seen early enough, labor should be induced by Krause's method (introduction of a bougie into the uterus) about the thirty-second to the thirty-fourth week of gestation; and even then, if necessary, deliver by version.

DR. H. P. C. WILSON said he had nothing to offer in regard to Dr. Neale's paper, except words of commendation, and he was ready to accept the teachings advanced. In his own practice, in cases of presentation of the breech demanding interference, he always brings down a foot. If the breech is engaged in the superior strait, he pushes it up into the uterus and brings a foot down, even if it is at the fundus uteri. He never exerts traction in the groin, either with his finger or the blunt hook, and never uses forceps in such cases. With greater experience, turning grows more and more in his favor.

He referred to the confinement of the wife of a friend in Copenhagen, in which case the head presented. After prolonged effort and failure with forceps, the child was removed by embryotomy. He felt certain, from the account he received, that, had turning been resorted to early, there would have been very fair prospects of saving the life of the child.

DR. B. B. BROWNE had succeeded twice lately in delivering the child with Tarnier's forceps, in difficult breech presentations, where the membranes had been ruptured several hours, the vagina hot and dry, and the breach firmly fixed in the superior strait. In a similar condition, several years ago, he had applied Elliot's forceps, but it slipped and failed to deliver the impacted breech. In all cases where the membranes are unruptured, or where the breech is not firmly wedged in the pelvis, he would prefer bringing down the feet rather than using forceps.

In reply to a question, Dr. Browne said he applied the forceps in these cases to the sides of the pelvis of the mother, and without reference to the portion of the breech upon which the blades would press.

DR. NEALE, in reply to a question, said, that in the first case reported, the blades of the forceps clasped the child over its hips. He thought, however, that the forceps would have a better hold if one blade was over the sacrum and the other over the anterior aspect of the opposite thigh, which is the method recommended by Dr. Lusk.

DR. THOMAS OPIE highly approved of the teachings set forth in Dr. Neale's paper. In practice he always makes due effort to bring down *both* legs in decomposing the impacted breech or in turning the child. The hand grasping both knees or one knee or thigh, has always a more secure hold than by a foot or even both feet, and the traction acts more directly and efficiently on the body.

DR. NEALE, in reply to Dr. Wilson's remark, said that he "always went for a foot" in breech cases requiring interference, and that he believed there were many cases in which it was practically impossible to bring a foot down, as when the breech already occupied the pelvic cavity and could not be pushed up into the uterus so as to free a foot.

CORRESPONDENCE.

ABSORBENT COTTON AS AN ELECTRODE COVERING.

To the Editor of THE MEDICAL NEWS.

SIR: Any new thing presented to the profession in a scientific journal being properly open to adverse criticism, I welcome the exceptions taken by Dr. Faught in the last number of THE NEWS to my communication, on "Electrode Coverings," of December 26, 1885. But a few words will, however, be necessary to indicate his misconception of the meaning of my remarks.

If Dr. Faught had read my original article on this particular subject of minor electrotherapy, published February 7, 1885, to which the later communication was distinctly stated to be "additional," he could hardly have fallen into the error of mistaking the measurement of *wet* cotton and *wet* sponge for a measurement of either the specific or contact resistances of the dry materials. The object of either material, it was explained, is merely the maintenance of a layer of water to act as a conductor between the metal and the tissues. It is obviously absurd to speak of altering the contact resistance of a surface of *water* by pressure. The specific resistance of the compound conductor made up of sponge, or absorbent cotton and water, was the only resistance referred to, and its variability under pressure is readily understood by any one who reflects that heavy pressure makes the layer of water and cotton thin, and consequently a shorter conductor, while light pressure leaves this imperfect conductor longer. The subject is entirely foreign to Sir Wm. Thomson's remarks on the pressure of resistance of solid bodies (in which the resistance *increases* with the pressure).

The experiments were made to illustrate the varied resistances of these compound conductors under similar conditions of thickness and pressure. The actual amount of pressure was not measured, since no two persons press alike on an electrode, but the three degrees were selected as those likely to occur unintentionally during any application of electricity. Lacking these exact determinations of the pressure, any calculations of the ohms found are worthless for comparison, and only confusing to the general reader. The smaller resistance of wet absorbent cotton that is demonstrated by the experiments may or may not be a material advantage with an abundance of cells at command, but the later article points out a more important reason for its use at certain times, namely, the lessened *invariability* of the current under accidental differences of pressure on the electrodes.

Electrode disks can be as evenly covered with absorbent cotton as by cotton-cloth, patent lint, and chamois skin; but even if the disk happens to be covered very irregularly by the former substance, its superior water-absorbing properties will make it a more uniform conductor than the older materials.

Dr. Faught has kindly calculated for me the number of ohms that I must have found in the resistance of the two materials. The results are somewhat clouded by

the assertion that he allows "100 ohms for the metal circuit." That would necessitate the use of twenty-five thousand feet, or nearly five miles of copper wire, in my office, at the well-known rate of two hundred and fifty feet of wire of ordinary size to one ohm. The distance from the keyboard of my battery to the cellar and back is by no means so great.

I am, sir, very truly yours,

G. Betton Massey.

NEWS ITEMS.

The Female Physicians practising in Paris are now eight in number. The first on the list is Mme. Madeleine Brès, who received the title of Doctor in Medicine in 1875. Then Mlle. Clarisse Daniel, Health Officer, in 1876; Mme. Boucher, Doctor in Medicine in 1878; Mlle. Verneuil, specialist in cerebral disorders, Doctor in Medicine in 1879; Mlle. Rosa Perrée, Doctor in Medicine in 1881; Mlle. Benoil and Mme. Berline, Doctors in Medicine in 1883; and, finally, Mme. Inès Sâches-Serrante, in 1884.

Two female medical students, Miss Plunkett and Miss Blanche Edwards, passed the last competitive examination for hospital positions with success.—*Gazette de Gynécologie*, Jan. 1, 1886.

Consumption of Spirits in America.—The great drink cycle in this country has reached its highest point and started back on the descending scale. The Internal Revenue Department indicates that for the year ending June, 1885, this decline was nine millions of dollars less taxes paid than the year before; showing a greatly diminished production of spirits. From the same authority it appears that the number of persons engaged in the liquor traffic, who have paid special taxes to the State or Government, has steadily declined since 1883. These are unmistakable hints of the operations of the laws which govern the rise and fall of the production and use of spirits in this country.—*Quarterly Journal of Inebriety*, Jan. 1, 1886.

The Hungarian Minister of Education has asked M. Pasteur if he will receive a medical man sent by the Hungarian Government for the purpose of receiving instruction in the prophylaxis of hydrophobia. M. Pasteur has readily consented to the request; and Professor Babes, of Buda-Pesth, will probably be accordingly sent to Paris.—*British Med. Journal*, Jan. 16, 1886.

Dr. C. W. Kelly, of Louisville, Ky., has been elected one of the Vice-Presidents of the Section of Anatomy of the Ninth International Medical Congress.

Temperance in America.—At a meeting held on the 12th inst., at Prince's Hall, Piccadilly, the Venerable Archdeacon Farrer, D.D., gave an interesting account of his experience of the temperance legislation which exists in some parts of America. There are no less than five States of the thirty-six which have adopted a stringent measure of absolute prohibition, which has been productive of most beneficial effects. In the State of Maine the prohibitory law has been in force twenty-two years, and there is only one convict to every 1600 of the population; whereas in Massachusetts, where there is no liquor law, there is one convict to every 500 of the population. In Trimble county, Kentucky, which has adopted the liquor law, during the last year there has not been a single criminal case, not a single prisoner in the goal, and not a single pauper in the county. Kansas adopted the prohibitory liquor law in 1881, and during nine months of 1880, when it was under free whiskey rule, there were 264 convicts, while in nine months of 1881, when the prohibitory liquor law was in force, the number of convicts was only 148; and in a town in Illinois, with a population of 2500, there had not been a single arrest in twenty months.—*Lancet*, Jan. 16, 1886.

The Prevention of Myopia in School Children.—It is now tolerably well established that shortsightedness is developed and increased in a certain direct relation to the amount of school-work done by children. For the prevention of myopia, Fuchs, of Liège, in a prize essay, quoted in *The Birmingham Medical Review*, gives the following directions: First in importance are the arrangement and lighting of the schoolroom.

"The principal windows in England should look to the south or southeast. The long axis of the room should run north and south. Every scholar should, from his place, be able to see some portion of the sky. Light from above is the best, and, except in hot climates, glass roofs are very advantageous. The chief light must come from the scholar's left side. The height of the top of the window from the floor should not be less than two-thirds the width of the room. The total window surface should bear to the area of the floor a proportion of at least one to five. In artificial lighting by gas, every burner must have a glass chimney and a shade, the latter arranged to reflect the light down upon the desk, and to screen the scholar's eyes. There should be about one burner to every four scholars."

It is most important that the eyes should not be approximated too closely to the book. The proper position is that in which the shoulders and pelvis are parallel with the edge of the desk, and the head upright or bent but slightly forward. As to the construction of desks and seats, there must be several sizes to suit scholars of various ages; the distance between seat and desk, in the vertical direction, must be but little greater than the distance between the elbow and the ischial tuberosity. The edge of the desk must overhang the seat about two inches; the scholar can then sit upright. The surface of the desk must slope about one in five to obviate the bending forward of the head; and the breadth should not be less than fifteen and a half to sixteen inches. All stooping should be avoided, and the types used must be perfectly legible.—*British Medical Journal*, Jan. 16, 1886.

Paris Faculty.—Dr. Duclaux has been appointed to the new chair of Biological Chemistry in the Faculté des Sciences.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from January 19 to January 25, 1886.

Webster, Warren, *Major and Surgeon*.—Leave of absence further extended nine months on account of sickness.—*S. O.* 15, *A. G. O.*, January 19, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLVIII. SATURDAY, FEBRUARY 6, 1886. No. 6.

ORIGINAL ARTICLES.

THE RESULTS OF THE OPERATION FOR CONVERGENT SQUINT.[1]

BY D. B. ST. JOHN ROOSA, M.D., LL.D.,

PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

A RECENT English review of a work upon political economy remarks, "To our ideas, a State without statistics is almost as inconceivable as a mercantile or banking establishment without accounts."

I think we shall all agree that it would not be an overestimate of the value of statistics in our science and art, if we applied this statement of the critic to ourselves. In surgery, at least, we can hardly come to any very definite and positive conclusions as to the results of a given operation, unless the statistics of a sufficient number of cases have been carefully considered. And this is also true as to the course of any disease, or the effects of any drug. Impressions, however distinct, are not to be weighed against judicial conclusions formed from the study of a series of cases. Nor does an isolated case, however carefully observed, prove very much. Nowhere better than in medical science is the truth of the homely proverb exemplified, "It takes more than one swallow to make a spring."

It is, I think, owing to the lack of tables showing the results of a large number of cases, that the results of the common operation for convergent squint seem by a few authorities to be still an open question. About twenty-five years ago, Mr. J. W. Hulke[2] said that he was asked by an old ophthalmic surgeon of great reputation, "What do you honestly think of the operation for squint?" and he stated that a strong reaction still lingered against the division of the recti muscles. In order to do something to correct what Mr. Hulke evidently considered a prejudice against a useful and generally successful operation, he analyzed one hundred cases of convergent squint of which he has preserved the notes.

In 1867 Dr. D. Little[3] reported sixty-two cases of convergent squint, operated on by Mr. Thomas Windsor in the Manchester Eye Hospital.

In 1870 Mr. W. Spencer Watson,[4] in an article read before the Medical Society of London, inquires into "the causes of the occasional failure of the operation for squint," and gives an analysis of 99 cases of convergent strabismus. These tables all show a satisfactory percentage of cures. Mr. Hulke believes that the "removal of all disfigurement" was accomplished in 87 per cent. of his cases. Mr. Windsor's statistics show that more than 79 per cent. of his cases were completely successful. This proportion would have been larger had the patients been willing to submit to a second operation. Mr. Watson considers that he had a successful result in 73 per cent. of his cases, a partially successful in 12, and a slight improvement in 4, total 89 per cent. of cure or improvement.

It is now forty-five years since the operation of division of the recti interni muscles was first performed for the cure of convergent squint, and the general literature has been *nil*. There has been, however, very little tabulation of the results as to the removal of the deformity, and the restoration of the vision of the squinting eye. It was at one time quite generally believed that the loss of vision was caused by the deviation of the optic axis, and that vision could be restored if the patient was operated upon at a sufficiently early period. Schweigger's excellent monograph,[1] however, took up the question of improvement of vision after the operation, seriously, and pronounced it a myth, in spite of the isolated cases by excellent authorities that had been here and there reported, for example, by Steffan[2] and Knapp,[3] but even Schweigger does not furnish us with a general table of the results of the operation. The monograph is, however, rich in many details, and boldly opposes Graefe's view that there was such a thing as amblyopia from disuse of the eyes, which an early operation might avert. I believe that Schweigger's work has not yet been translated into English. Were it more generally accessible, I think the profession would soon be convinced of the incorrectness of the theory of an *amblyopia ex anopsia*. Certainly this would be so, did surgeons compile and study their own cases of squint.

From what I have heard of late, among experts in ophthalmology, general practitioners, and the laity, I suspect that the opinions as to the beneficial results of an operation for convergent squint are by no means as unanimous as they are, for example, as to the results of the operation for cataract. I find that it is still taught by some, that the vision of the squinting eye is improved by an operation; by others, that paralysis of accommodation by atropia will often do away with the necessity for an operation (Boucheron, John Green); by still another class, that the operation is performed too commonly, and should often be postponed, or even not performed at all; while Dr. Loring lately told me that he thought if there was anything we did know, it was how to cure convergent squint by an operation.

At the last meeting of the American Ophthalmological Society Dr. Seely (*Transactions*, p. 126) states

that: "Each year has strengthened the conviction that early operations (up to the twelfth or fifteenth year) are questionable, and should be entirely abandoned." On the other hand, Dr. Theobald, in the discussion upon this paper, states that there are few operations that he has found more satisfactory than tenotomy for convergent squint. So far as the discussion went, although it is fair to say that it was not participated in by many of the members of the Society, the impression is left upon my mind that at least some of these authorities are somewhat at sea on the subject of the results of the operation for convergent squint. Two of the members who participated in the discussion doubted the existence of loss of sight from disuse of the eye—*amblyopia ex anopsia*—a loss which was once generally thought to be recovered by an operation. Dr. Wadsworth, like Schweigger, is convinced that *amblyopia ex anopsia* is a myth.

A paper that gives no uncertain sound as to the value of the operation is that by Dr. Loring[1] published some thirteen years ago. Loring believes that it is true that "strabismus does sometimes disappear of itself, but it is an extremely rare occurrence, so rare, indeed, as to be the exception to prove the rule that it does not cure itself." After alluding to the want of unanimity of opinion among authorities as to the time for operation, Loring goes on to say that he is decidedly of the opinion that the cases in which the operation should be deferred to a comparatively remote period, are few in proportion to those that should be operated upon as soon as seen. Loring, however, furnishes no statistics. They would have been a fitting termination of his suggestive and philosophic paper. Loring says, in this article, that "in certain cases when only one eye is habitually used, the vision deteriorates, so that the eye in a short time becomes useless." The mobility of the squinting eye outward, he also says, is greatly reduced. I think if Loring had tabulated his cases, and carefully investigated the subject of deterioration of vision, he would not have adopted Graefe's views in this respect, but, like Schweigger, would even declare such a deterioration to be mythical, or doubtful at least.

Tables comprising a scant 300 cases, are certainly not enough to determine the results of the operation for strabismus. These are all I have been able to find after a careful search. It is in this lack of statistics, that is, I think, to be found that failure of ophthalmologists to formulate their views on this subject with general unanimity, and to settle the question as to whether vision is, or is not, deteriorated by the continuance of a squint, whether there is, or is not, an *amblyopia ex anopsia*. Certainly it is not from want of material that the statistics of the results of the operation for convergent strabisimus are so meagre. It is one of the operations most frequently performed by oculists. One writer states that he has performed 3000 tenotomies,[2] and yet, so far as I am aware, no statistics as to the results of his operations have appeared in print, while the results of cataract extraction, and of iridectomy for glaucoma, have been presented to us in all the varied tables that skill can suggest, and with the greatest advantage to our exact knowledge, so that discussions as to the general results or the utility of the operation are not even thought of. The important operation to relieve a very distressing deformity, a deformity which alters the whole character of the human face, remains as yet without sufficient data, in this country at least, to enable a body of experts to determine positively whether or not visual power is impaired by such a deviation of the axis of the eye, and such a displacement of the *macula lutea*, as results from squint, and members of this same body appear also to differ materially as to the value or propriety of an early operation. In view of the facts, I have been led to think that a table of the cases of strabismus convergens, in which the notes show the results of the operation of division of the internal rectus, would be of some value at least, and perhaps lead to the publication of others. To me, at any rate, they seem to be enough to prove one point, and for this reason I venture to publish them. Of the etiology of strabismus convergens I do not intend to speak with fulness, but I simply desire to indicate, so far as a hundred and eleven cases will show, what we may expect in the correction of the deformity, and in improvement of the vision of the deviating eye.

With a few exceptions, until the introduction of cocaine as a local anæsthetic, I have used ether for the purpose of procuring general anæsthesia during the operation. Occasionally I have operated without an anæsthetic. In later days I use cocaine in all self-contained subjects, young or old, and ether in children of a nervous or excitable temperament. I make cold water applications for some six hours, by means of pieces of cloth made cold by being laid upon a block of ice. No suture is applied to the conjunctival wound.

In making the table appended to this paper, all cases in which the result is not positively known have been rigorously excluded. Until the last few years, I have been unable to have proper notes taken of my hospital cases, so that I have been obliged to be satisfied with a report of the tenotomies, one hundred and sixty-eight in number performed upon one hundred persons. These, however, have been carefully observed so far as the results are concerned, although I regret that the data in some respects are very meagre. An analysis of the general table which is the conclusion of the paper, shows the following facts, one of them at least is well appreciated already, that is, the proportion of hypermetropia in strabismus convergence is every large—98 per cent. That I have found no emmetropic eyes, as Schweigger does, is to be explained by the fact that I have estimated the refraction while the patients' eyes were under the influence of atropia. When the ciliary muscle was completely paralyzed by atropia, in all my cases of convergent squint except in those that were myopic, I have always found that vision was clearer and in most instances markedly better with a convex glass. That there are eyes not myopic that never accept a convex glass, even when fully under the influence of atropia, I have long since shown[1] and this has been verified by another observer, Randall.[2] That there is an

[1] Transactions American Ophthalmological Society, 1873.
[2] American Journal of the Medical Sciences, July, 1885, p. 147.

emmetropic eye, although it is an ideal one, I think is clearly shown by these observations, but as compared with hypermetropia or myopia, emmetropia is an exceedingly rare condition.

Even if we consider an eye emmetropic that accepts only a convex sixty after full paralysis of the ciliary muscles with atropia, it will be seen, by reference to the table, that there is very little of this kind of emmetropia in cases of convergent strabismus, the hypermetropia being usually as much as a $\frac{1}{48}$th or more. Yet I think all experts have long since abandoned the belief that convergent strabismus is *chiefly* dependent upon hypermetropia. The short antero-posterior diameter of the eye is but one factor, if it be one at all, in the production of convergent squint. Else excluding the myopic, three-quarters or more of the human race would squint.

In the congenital amblyopia of one eye, which I believe is the general condition of patients with convergent strabismus, and the resultant loss of single vision with two eyes, is perhaps to be found the important fundamental condition for the production of convergent strabismus.

In two cases of myopia with convergent squint, the myopia was so considerable that the far point was at less than seven inches. Both of these cases occurred in females, and in both of them parallelism resulted from the operation. In the case of upward squint, which is still under observation, I propose to bring forward the inferior rectus and again divide the superior rectus. It is the only one of these cases in which the result is as yet entirely unsatisfactory, for in the cases of convergence still remaining, or in the cases of divergence, a simple remedy is still at hand. In the cases of convergence when but one muscle has been divided, I do not consider that the operation has been fairly tried, for I invariably inform my patients that from one to four operations will be required, and I only undertake cases when I am allowed to use my own judgment as to the propriety of a second or even third or fourth operation.

One of the most successful cases that I have ever operated upon, in point of correction of the deformity, and one which is not included in this table, was that of a young man of about thirty years of age, upon whom I performed successive operations, each time making a distinct gain: and I know this is not an entirely unusual experience among those who operate much for squint. The opponents of the operation for convergent strabismus assert that divergence very often results. I have not seen this in my own practice, nor in that of my colleagues and my friends in other institutions than that in which I am a surgeon. I see, however, many successful cases, of years' standing, among the patients who apply for correcting glasses at my clinic. The cases of divergence which I have seen and upon which I have operated have been usually, if not always, cases that came from the hands of travelling oculists without professional standing. The cases of slight divergence that now and then occur in the most experienced hands, may be usually corrected by division of the external rectus without advancement of the internus.

With Loring, and I believe in common with most of the profession in our country, I think the best time for an operation is from five to seven years of age, when occupation with small objects and strain of the accommodation are about to begin. To operate earlier than this, is to lose the great advantage of assistance in correcting the squint that may remain after one or two tenotomies, by the means of convex glasses. As a rule, I advise that glasses be finally left off except for near work, in all cases where the manifest hypermetropia is not great, and when distant vision is not markedly improved by wearing them. Although I have faithfully tried the method of curing squint by the use of atropia and glasses, without operation, I have had no good results, and I have well-nigh abandoned it, although I attach much importance to the use of atropia and glasses after a partial result from a tenotomy.

I can only speak of the practice of allowing children to go from six or seven years of age to the period of puberty, to be jeered at by their thoughtless playmates, without correction of a squint, as being, in my opinion, indefensible and dangerous to the nature and development of the child thus neglected. That some children grow out of squint is, of course, not to be denied, but a few months of observation will determine which those are, and thus prevent an unnecessary operation.

32.	20/XL		20/XXX	

A reference to the general table will show that the hypermetropia or hypermetropic astigmatism was almost always of a considerable degree, from a 36th to a 3½, and that there was almost always amblyopia of one eye.

These tables comprise all the cases in which exact notes show that the visual power was increased after the operation. I purposely say *after*, because the improvement of vision that is sometimes seen after a successful operation for strabismus convergens is, I believe, merely a *post hoc* and not a *propter hoc* occurrence. After I have performed an operation for strabismus, if the effect be not sufficient, in common with all surgeons, I suppose, I paralyze the ciliary muscle with atropia, and keep up this effect until it is shown that another operation is needed. It is during this stage that glasses are fitted. Inasmuch as the first examinations take place when the eyes are not under the influence of atropia, only the manifest hypermetropia is shown. In a certain proportion of cases we get a marked or slight improvement of the sight, especially of the squinting eye, with the appropriate glasses, or perhaps without.

But this improvement, which, as will be seen by reference to the table, is generally slight, *is not due to the operation, but to the letting up of the spasm of accommodation.* But in many instances this improvement is so slight, for example, from $\frac{20}{XL}$ to $\frac{20}{XXX}$, from $\frac{162}{CC}$ to $\frac{20}{CC}$, as to lead us to suspect that there may have been an error in the first examination.

In a discussion in the New York County Medical Society, some years since, upon the subject of apparent improvement in vision immediately after the use of strychnia, Dr. O. D. Pomeroy called attention to the fact that many patients have to be trained to see what they actually are able to see. Hence a second examination by test-letters often shows that a patient can read one more line than he did at the first, simply because he had learned how to pass this ordeal of picking out letters.

Schweigger reiterates this well-recognized fact, and warns the practitioner not to be sure that his patient actually sees more, because he reads another line or two on the second trial of the test-letters. Certain it is that this table gives no encouragement to the theory of an *amblyopia ex anopsia*, a loss of sight from disuse of the eye.

As to the cases in which I am not able to state positively what the vision was before and after the operation, I can only say, from pretty distinct recollection, that in no case was there any improvement in vision that could not be explained by the result from adapting proper glasses under atropia. The only case that I have ever personally seen, where any color is given to the theory of amblyopia, or deterioration of vision from disuse of the eye, is that of a squinting and hypermetropic female, in which my records state as follows: "Age seven, February 11, 1880. Periodic convergent squint, R. V. $\frac{20}{XX}$—; L. V. $\frac{20}{XX}$—. February 18, same year, under atropia,

both eyes $\frac{20}{XX}$ —; w. + $\frac{1}{8}$; wears + $\frac{1}{10}$. May 3, 1884. R. V. $\frac{20}{L}$; the same with a convex 10; L. $\frac{20}{X}$; accepts + $\frac{1}{10}$. The right eye is the squinting eye."

The record of the vision in 1880 was made by the late Dr. Edward T. Ely, and, I have no doubt, with his usual care and accuracy. The vision at final examination, when the squint was fully established, was made by Dr. J. B. Emerson. In this one case the lapse of four years does seem to have blunted the vision of a squinting eye. I doubt not, however, that the use of atropia and glasses, without an operation, would have very much increased the vision of this squinting eye.

This patient declined an operation at my hands, and was subsequently operated upon at a public institution, but no records of the result could be found.

That there may be a certain slight amblyopia due in a sense to the squint I do not deny, but this is usually trifling, and only indirectly caused by it, and should be considered apart from the congenital amblyopia, sometimes, and even usually, of a high degree, which, as I have before said, is one of the fundamental conditions of strabismus convergens.

I am very glad to be able to append to my table of 100 cases eleven additional ones, that were operated upon by Dr. F. M. Wilson, of Bridgeport, Connecticut, who, very kindly, gave the notes to me for publication. It will be seen that his results tally with those furnished by the larger number. In a few cases the final record of the patient's vision makes it slightly less than before the operation. As will be seen by referring to the general table, these cases of decrease of vision may be set down to incorrect observations either at the first or final examination.

COSMETIC RESULTS.

Parallelism resulted in	79
Convergence remained in	16
Divergence in	4
Upward squint	1
	100

When convergence remained but one tenotomy has been performed, in	10 cases.
Two tenotomies in four cases	4 "
Three tenotomies in two cases	2 "
	16 "

From these results, as well as from the impressions derived from experience in many more cases, the histories of which are not complete, I conclude that the following propositions are indicated:

1. The operation for convergent strabismus is successful in removing the deformity in from seventy to eighty per cent. of the cases operated upon.

2. When complete control of the patient may be obtained, and as many tenotomies as are necessary are performed, this percentage may be easily raised to more than ninety-five.

3. No essential improvement of the vision of the squinting eye arises as a result of the operation.

4. After parallelism of the optic axes has been secured, glasses may be worn that, in some cases, give an increased vision in the formerly squinting eye.

5. The loss of sight in a squinting eye is probably a congenital amblyopia, the nature of which is not exactly, if at all, known, and which is as yet incurable.

6. No substitute has, as yet, been found for the division of the recti muscles for the cure of squint.

I do not, for an instant, think that this paper, nor these conclusions, are anything more than a small contribution to the study of strabismus. Many points have not been even alluded to, but I think enough has been here shown to stimulate to further study of the subject, and to justify a continuance of our esteem for the illustrious Dieffenbach, who, on the 26th of October, 1839, first divided the internal rectus on the living subject for the cure of squint.

ON THE CONNECTION BETWEEN OBSTRUCTION OF THE LACHRYMAL DUCT AND NASAL CATARRH.

BY HARRISON ALLEN, M.D.,
OF PHILADELPHIA.

WHILE treating a case of chronic nasal catarrh, which chanced to be confined to the right side of the body, I was struck with the fact that the lachrymal passage on the same side became inflamed and the lachrymal sac distended at the same time that the treatment was progressing toward recovery. It was at least a strange coincidence that the obstruction should have occurred on the side corresponding to the chronically inflamed nasal mucous membrane, and the circumstances led me to make inquiry as to the frequency of the occurrence of lachrymal obstruction in chronic nasal disease.

As a result of my interest in the matter, I have come to the conclusion that the two conditions are not infrequently associated. The duct is obstructed in two classes only, namely, in chronic nasal catarrh, in which there are submucous infiltrations and atrophies, and in cases in which the bony walls of the nasal chambers are attacked either by osteitis or necrosis.

Through the courtesy of Dr. William F. Norris and of Dr. Charles A. Oliver, I have lately had an opportunity of examining a number of patients of the dispensary service at the Wills Hospital, and have been surprised to find that in every instance in which the lachrymal duct was obstructed, chronic nasal catarrh was also present. Twenty patients were examined in all. It would be a mistake in judgment to conclude that these figures represent the true numerical relation which exists between the two affections. As is well-known, the reception rooms of our large dispensary services exhibit a greater number of inveterate and unusual diseases than will be found in an equal number of patients in private practice. In my own practice, I have met with but three instances in which the affections were coincident. One of these has been alluded to above. The second was met with in a man, sixty years of age, who had an offensive discharge from the right nostril, and obstruction of the lachrymal duct of the same side. The patient declared that the discharge from the lachrymal sac often had an offensive odor, the odor, indeed, of the nasal discharge itself. It was

never purulent, however, and exhibited the appearances usual in lachrymal disease. In the third case the ducts were obstructed on both sides. The nasal chambers were covered with atrophied mucous membrane, and when first seen were occupied by the characteristic discharge of the advanced stage of the affection.

The lachrymal crests, in all cases examined, were either too prominent or too small. Apart from these trivial characters, no peculiarities of the osseous parts could be detected.

On page 421 of the English translation of Stellwag von Carion's *Treatise on Diseases of the Eye* occurs the following language: "It [blennorrhœa of the lachrymal passages] is frequently developed by a propagation of inflammation from the neighboring parts to the lachrymal passages. Especially important in this regard are inflammations of the nasal mucous membrane, the edges of the lids, and the conjunctiva." The author, in continuation, names the nasal conditions which may induce lachrymal disease, and he places in the first order "severe and long-continued nasal catarrh." Notwithstanding this dictum, the connection appears to have been to a great extent overlooked by later observers, and it is consistent, under the circumstances, to restate the facts.

MEDICAL PROGRESS.

Paludism and Pregnancy.—In a recent study by Bonfils (*Thèse de Paris*, 1885) the following conclusions, based on 140 observations, are presented:

1. Abortion is far from being the rule in women attacked with paludism during pregnancy. Premature delivery, however, is frequent.

2. The accidents induced by paludism are due to congestion of the uterus and its lining membrane, produced in the state of chill.

3. Pregnancy gives no immunity from malaria, and may sometimes awaken that diathesis.

4. Acute paludism renders labor active, but the cachexia appears to have the opposite effect.

5. In the parturient malarial sufferer the pulse is not so slow as is habitual; there is no diminution in temperature, retardation of uterine involution, frequent hemorrhage, and the lochia are not abundant.

6. A return of paludism after parturition is very frequent.

7. The sulphate of quinine has no ecbolic action, and should be administered to the pregnant woman and the nurse when affected with malarial fever.—*Gaz. Méd. de Paris*, Jan. 2, 1886.

Physiological Action of Amyl Nitrite.—In contradiction to the usual statement, that nitrite of amyl effects a lowering of the blood-pressure, Schweinburg maintains that in small doses, as ordinarily exhibited by inhalation, this agent produces a rise of arterial pressure to the point at which there appear flushing of the face, carotid pulsation, and sensations of heat. These observations, which were made on men by means of the sphygmomanometer, are reconciled with the statements of previous observers by a series of experiments on dogs, in which it was shown that large doses, or often repeated small doses of the nitrite produce a diminution of arterial tension.—*Centralb. f. d. med. Wiss.*, Jan. 2, 1886.

Papayotin in Diphtheria.—Kriege has employed papayotin in five per cent. solution as a local solvent in diphtheria and croup, in some fifty-eight cases. After emphasizing the necessity of employing a reliable preparation of the drug, he states that while papayotin is no specific in diphtheria, its application is of great benefit, and absolutely without danger. It was shown to be of especial value in tracheotomy. The so-called infiltrated forms of diphtheria are uninfluenced by the drug.—*Centralb. f. d. med. Wiss.*, Dec. 19, 1885.

Carbolic Acid in Phthisis.—Tilleau records several cases in which the symptoms of pulmonary phthisis have been greatly ameliorated by the use of carbolic acid, especially in hypodermatic injection. Stress is laid upon the necessity of purity in the acid, which should be absolutely white, and should not become discolored by keeping. A one per cent. solution is used, which, it is claimed, never causes the formation of abscesses.—*Journal de Médecine*, Jan. 3, 1886.

Tupelo in Dilatation of the Uterine Cervix.—Ménière regards the tupelo root as preferable to sponge or laminaria for the following reasons:

1. Tupelo acquires its maximum degree of expansion in less than an hour and a half, while sponge and laminaria require from six to seven hours.

2. Its surface remains soft, pliable, and spongy, and in extracting it there is no danger of injury to the mucous membrane.

3. It returns with facility to its former size and shape, and may be used several times if subjected to disinfection in mercuric chloride after each operation.—*Gaz. de Gynécologie*, Jan. 1, 1886.

Internal Use of Carbon Bisulphide.—The *Pharmaceutical Record* for Jan. 15, 1886, quotes the account given in the *Répertoire de Pharmacie*, 1885, p. 541, of the observations of Dr. Sapelier. This observer has shown that *pure* bisulphide of carbon is not at all poisonous when given by itself, but immediately becomes so when given together with alcohol or to persons who use alcoholic beverages, because then sulphuretted hydrogen will be formed. With these precautions he regards it as an invaluable antiseptic remedy in typhoid fever, and all intestinal diseases accompanied by putrid fermentations.

Chemically pure bisulphide of carbon	10 parts.
Distilled water	500 parts.

Mix and keep in a black or amber bottle. Of the *decanted* water give 6 to 20 tablespoonfuls in the 24 hours, either in lemonade or in milk.

Venesection for Hemorrhage.—A correspondent of a Madrid medical journal, writing from Zaragossa, says that in cases of hemorrhage, notably in hæmoptysis and in epistaxis, if astringent remedies fail to arrest the attack, the simplest and best proceeding is to open the saphena or basilic vein. So far from alarming the patient and his friends, he finds that it rather tends to reassure them, for there is an idea very prev-

alent in Spanish towns that "a doctor who does not bleed is not a good one." Many patients, too, with epistaxis will exclaim that they would rather die than allow an instrument to be passed into the nostril, but they will readily consent to allow a vein to be opened, especially when they are assured that this proceeding will almost infallibly cause the flow of blood from the nose to cease. The writer says that this assurance may be given with the utmost confidence, as he has constantly employed venesection for this purpose with very great success.—*Lancet*, Jan. 16, 1886.

Microbiological Study of the Lochia.—Fasola presents, in the *Annali di Ostetrica*, the following results of his microscopic studies of the lochia in four various conditions:

1. Microörganisms are constantly to be found, both in normal and pathological lochia, several hours after delivery, even when carbolized or mercurial injections have been given during the labor. The most usual form is the micrococcus; bacilli are rare.

2. In normal labor, and in the absence of any prophylactic medication, their number is very small; they augment in the first few days, and disappear about the seventh or eighth day.

3. If vaginal injections be given during labor, the growth of microörganisms is retarded. They are found in greatest number when the lochia are altered by puerperal ulcerations or by endometritis, but after intrauterine injection their number diminishes notably.

4. On repeating the carbolized intrauterine injection every day during the puerperal period, the microorganisms remain infrequent, even in fetid lochia. The number is still smaller if solutions of corrosive sublimate are used.—*Arch. de Tocologie*, Dec. 1885.

Effects of Diastatic Ferments on Coagulation of Blood.—Salvioli, of Genoa, has shown that the diastatic ferments have the property of preventing blood coagulation in much the same way that peptone produces this effect. The ferments employed were vegetable diastase, the amylolytic ferment of the liver, and ptyalin. The first two of the ferments named were found to give the most marked results, and when injected into the circulation in the amount of from 0.06 to 0.08 of one per cent. of the weight of the animal, rendered uncoagulable the specimens of blood removed from time to time for an hour and a half after the injection. The best results were obtained with dogs, the method being practically without effect on rabbits and guinea-pigs.—*Centralb. f. d. med. Wiss.*, Dec. 19, 1885.

Soothing Application in Neuralgia.—Mayet has presented, before the Société de Thérapeutique, the following formula for a very neat and compact local application for use in neuralgic affections:

Chloral hydrate	5 parts.
Crystallized menthol	5 "
Cacao butter	10 "
Spermaceti	20 "

These constitutents are mixed into a paste, which is divided into pieces about two-fifths of an inch square, and weighing about thirty grains.

Chloral thus applied in cacao butter has no local irritative effect. The part affected is to be gently rubbed with one of the squares, which is then allowed to melt at the most painful point.—*Journal de Médecine de Paris*, Dec. 27, 1885.

Use of the Œsophageal Sound after the Operation for Harelip in Infants.—The use of an appropriate œsophageal sound, after the operation for harelip in infants, is strongly commended by Bar, as being of direct benefit in two ways.

First, all sucking movements of the lips, with consequent danger to the sutures, are avoided; and, second, the food does not come in contact with the wound. According to Bar, the introduction of the sound is readily effected in infants, and is entirely without danger.—*Centralb. f. d. med. Wiss.*, Jan. 16, 1886.

Artificial Suppression of Menstruation in Chlorosis.—Löwenthal, of Lausanne, reports his observations on twenty-three cases, in which the artificial suppression of the menses proved a valuable therapeutic measure.

The method employed consisted in injections of hot water, of at least 120° F., with close restriction to bed. In very rare cases, ice water was found to be preferable to hot water.

Eighteen of the cases described were chlorotics, and the remaining five included two cases of severe hysteria and three convalescents from exhausting diseases. In the cases last named, a shortening of the period of convalescence was effected. One of the hysteric cases was markedly benefited, and all of the chlorotics were cured with surprising rapidity, and without further medication, after from two to five suppressions. Evil consequences were in no case noticed.—*Wiener med. Presse*, Dec. 13, 1885.

Presence of Peptone in Pathological Organs.—Mitra has set before himself the query whether any non-bacterial influences which cause the destruction of living tissues induce at the same time a production of peptone. In attempting to decide this point, phosphorus, the destructive action of which upon tissue-albumin is well known, was chosen. In rabbits poisoned with this drug, peptone was constantly present in the liver, heart, and kidneys; in the liver to the extent of 0.14 to 0.76 per cent. of the weight of the fresh organ. Similar results were obtained in the case of a dog poisoned with the same drug. Control experiments gave negative results. In six fatal cases of puerperal fever peptone was constantly present in the liver on an average to the extent of 0.59 per cent. of its weight, and was usually present in heart and spleen.—*Centralb. f. d. med. Wiss.*, Jan. 16, 1886.

Hydrocyanic Acid as a Result of the Fermentation of Flaxseed.—Jorissen, in the *Bulletin of the Royal Academy of Belgium*, has shown that a mixture of flaxseed meal and warm water exposed to a temperature of 80° F., will, upon distillation, yield a certain quantity of hydrocyanic acid. This observation has been confirmed by Senior, who has further shown that the result in question is not due, as had been supposed, to the presence of any adulterant in the flaxseed. The application of these observations is evident.—*Les Nouveaux Remèdes*, Jan. 1, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA

SATURDAY, FEBRUARY 6, 1886.

THE NEW YORK STATE MEDICAL SOCIETY.

THE eightieth annual meeting of this Society was held at Albany this week, and a full account of its proceedings, received by telegraph from our special reporter, appears in this issue of THE NEWS.

The meeting was largely attended, and the papers presented were numerous and of more than usual interest and scientific value. The President, in his Inaugural Address, calls attention to several ways by which it is thought the influence and usefulness of the Society may be extended. His remarks in reference to the organization of the Washington meeting of the International Medical Congress, if only from the fact that they represent the views of such a large and influential body of the profession as that composing the Medical Society of the State of New York, command thoughtful consideration.

Of the scientific proceedings, we can now only call attention to some brief remarks on the subject of gymnastic training, by Prof. Loomis, which will be read with special interest, since nowadays physical training has become a fad, and athletic sports occupy a prominent place in the college curriculum. Dr. Loomis's word of warning, based on a large clinical experience, is timely, and must lead to a more careful and exact consideration of the whole subject from a medical standpoint, than it has yet received in this country. The statement that our young men are overtrained, and that thereby the foundations for cardiac and pulmonary disease are laid, although coming from such high medical authority, will not go unchallenged. The public will anxiously look for the data upon which these views are based, and we hope that Dr. Loomis will lose no time in making a full presentation of them.

THE PROSPECTS OF NATIONAL PUBLIC HEALTH LEGISLATION.

THAT it is very desirable that the present Congress should adopt some measure which will provide for a permanent national sanitary bureau seems to be generally admitted. It is also the opinion of the great majority of physicians and sanitarians, as well as of members of Congress, that it is useless to attempt to rehabilitate the present National Board of Health. It has become evident to most of the friends of the National Board that no satisfactory results can be expected from it under the existing law, owing, mainly, to the fact that it is connected with a department which, if not actively hostile to it, is, at all events, by no means disposed to aid it

Under these circumstances the representatives of the American Public Health Association and of the Association of State Boards of Health seem to have come to the conclusion that the best thing to be done is to give up the idea of a board of health as a part of the machinery of the general government, and to create instead a bureau of health, in the Department of the Interior, which bureau shall have at its head a Commissioner of Health, and the general organization of which shall be analogous to that of the Bureau of Education.

The bill for this purpose provides that the Commissioner of Health is to perform substantially the same duties as those which were assigned to the National Board by the Act which created it, viz., to collect and diffuse information on matters relating to public health, to make investigations into the causes of disease and the best methods of their prevention, and to publish in a weekly bulletin such statistical and other information relating to these subjects as it may be able to obtain.

The Department of State, through its consular officers, is to furnish the bureau with information as to the sanitary condition of foreign ports, and especially as to the occurrence and progress of pestilential disease abroad.

The Commissioner is to be the official adviser of the Government on all questions affecting the public health, but he has no executive duties or powers, and he is to have nothing to do with quarantine work in this country.

The bill seems to be simple and practical, and one of the passage of which there is a fair probability.

There is certainly not the least probability that Congress will give any funds to the present National Board, or that the Executive will entrust it with duties or moneys, nor is it probable that Congress can be induced to pass any law organizing a national board on the principle of State representation.

It seems, therefore, advisable that all who favor the creation of some kind of national sanitary organization should aid the officers of the American

Public Health Association in their efforts to secure the passage of the bill above referred to, even though they may think that the bill does not confer such duties and powers as they would like to see vested in the Department of Public Health of the United States.

Besides the question of a sanitary bureau, Congress has before it the question of the creation of a special Commission to visit South and Central America, and investigate the truth or falsehood of the alleged discoveries of Freire and Carmona with relation to the specific microörganism of yellow fever, and the possibility of protective inoculation against this disease. The proposal to send such a Commission has been presented by Dr. Joseph Holt, the President of the State Board of Health of Louisiana, in behalf of the American Public Health Association, and seems to meet with the approval of the committees of the House and Senate, to which it has been referred for consideration.

While we have serious doubts as to the accuracy and value of the conclusions reported by either Freire or Carmona, and it may be noted that their conclusions are very discordant, we do believe that they are on the right road as to methods of investigating the specific cause of yellow fever, and that the creation of the Commission as proposed by Dr. Holt is an eminently proper and judicious piece of legislation on the part of Congress.

SAVING THE PERINEUM.

MANY of our readers will remember that in antebellum times "saving the Union" was an expression in common use, by some in all sincerity, by others in irony. Saving the perineum, that is, saving it from rupture, is becoming quite as common an expression in medicine as saving the Union was in political affairs during the few years that preceded our civil strife.

Methods of saving the perineum from being torn in childbirth are presented annually, semi-annually, almost quarterly, until they threaten to be as numerous as uterine specula. If a new method cannot be devised by the ingenuity of an obstetrician, an old one may be revived, and proclaimed upon the basis of infallible statistics to be the right one. Possibly it may suggest itself to some minds that the very multiplicity of means proposed to prevent perineal tears, is proof that no one is always efficient, and that in some cases the perineum will be ruptured no matter what method is used. The truth is, several factors enter into the production of these lesions, as, for example, the form of the perineum, the condition of its tissues, the size of the child, the presentation and the position, the character of the expulsive force, the conduct of the patient, etc.

We have been led to make these reflections from an article by DR. MEKERTTSCHIANTZ, in a recent number of the *Archiv für Gynäkologie*, upon tearing of the perineum and protective means. The method he advocates for preventing such tears is that of relaxation of the perineum. While he acknowledges the general plan an old one, having been recommended by Flamant, Weigand, Busch, Velpeau, and others, yet he claims that no one has hitherto made a positive method of it—that it has not been used systematically.

While directing that the method must be suitably modified according to the presentation, he gives the following description of it as applied to ordinary vertex presentations. The patient lies on her back, the lower limbs are flexed, but the knees must not be so widely separated that the perineum is at all stretched. When the presenting part presses the perineum forward, the obstetrician sitting on the woman's right side, grasps with the thumb of the right hand the right side, and with the fingers the left side of the perineum, trying to relax each side. As soon as the head enters the vulval orifice and the frænulum is stretched, the left hand is carried over the woman's right thigh, and placed with the ulnar margin on the mons veneris, so that the thumb over the right labium and the middle finger over the left labium, grasp the frænulum from each side, and, as the thumb and finger approximate each other, it is relaxed. The presenting head, now in the vulval cleft, is, by means of the vola of the left hand, subjected to light interrupted pressure, and emerges between the fingers placed at the sides. After the birth of the head, the left hand disengages, if necessary, the navel cord, and is then used for completion of the delivery of the child, while the right is relaxing the perineum during the expulsion of the shoulders.

The results of this method in the author's hands are remarkable, for out of fifty primiparæ, in only two was there a trifling rent of the mucous membrane observed. The method is undoubtedly a good one, but it promises too much, for one is always sceptical in regard to an infallible remedy. Moreover, the position in which Mekerttschiantz places the parturient, on her back, is one in which the perineum is more liable to tear than if she lie on her side.

MITRAL STENOSIS.

IN the January number of *The American Journal of the Medical Sciences* there are, among several important papers on heart affections, two upon mitral valve disease and its symptoms, which are worthy of special consideration.

DR. AUSTIN FLINT discusses the mitral cardiac murmurs and their significance, while DR. BROADBENT, of London, deals exhaustively with the subject of mitral stenosis, to some of the general features of which we propose, on this occasion, to refer.

Among the peculiarities in the clinical history of this common affection which still lack a suitable explanation, is the frequency of it among women. The estimates of various authors given by Dr. Broadbent, range from 66.6 per cent. to 78.75 per cent. Girls are more subject to rheumatism than boys, and the greater liability of girls to anæmia at the period of puberty may be a factor in inducing the valve disease. The greater prevalence of chorea in girls, and the well-known predilection of the endocarditis, in this disease, for the mitral valves, are, we think, important causes of the greater frequency of mitral affections in women. The endocarditis resulting in sclerotic changes is an insidious process to which the acute warty form is related only as an excitant. The valvulitis in rheumatism, chorea, and scarlet fever is usually harmless, as such; the little beady excrescences soon disappear, but irrevocable damage results from the tendency, which so often remains, to slow proliferative changes, by which the valve tissues are gradually sclerosed and the segments deformed. Dr. Flint remarks on the frequency with which the lesion is met with in persons who have never had rheumatism.

Another unsettled question relates to the existence of this lesion in children. Dr. Broadbent has had more cases of advanced mitral stenosis in children than any other serious form of heart disease. The experience of individual observers is by no means unanimous on this point. Hayden, Fagge, Sansom, and Loomis, speak in much the same terms as Broadbent, but Duckworth's statistics do not support this view, nor do our own more limited observations. Of twenty-three cases examined after death, the youngest was seventeen. Excluding congenital cases, we should say that mitral constriction is rare before puberty, much more so than a curling of the edge of the curtains with the production of marked incompetency, without much, if any, narrowing of the orifice.

The pulse of mitral stenosis is usually described as small, feeble, and irregular, but in Broadbent's experience it is almost invariably regular until failure of the heart occurs, when the irregularity may become indescribable and it is impossible to time sounds or murmurs. Cases, however, go to a fatal termination with little or no disturbance of rhythm. There is a modified high-tension—*i. e.*, the artery is small, but is full between the beats and can be rolled under the finger. Mitral stenosis is usually regarded as the lesion most likely to be associated with general cardiac dropsy, but Broadbent holds that in uncomplicated cases this symptom may be absent until very late in the disease or may never appear. He has met with an extreme degree of anasarca only when the tricuspid orifice has been narrowed. The records of Guy's and of St. Mary's Hospitals certainly bear out this statement.

While all authors are agreed that aortic incompetency is the most serious of heart affections, there is still a difference of opinion as to the next in gravity. Broadbent unhesitatingly gives the place to mitral stenosis, and yet his figures show the average age at death to be for males, 33, and 37 or 38 for females. This is a high average for an affection which, as many authors state, is especially met with in the young. The special danger is believed to be connected with the greater difficulty in the establishment of full compensation. But is this so? Do we not frequently meet with well-marked cases of mitral stenosis going about and enjoying life undisturbed by the consciousness of heart weakness? As Broadbent says, they often have not, up to an advanced stage, the look of heart disease, being neither pallid nor anxious looking, nor livid and dusky. Up to the very moment of the onset of serious symptoms the patient may be unconscious of cardiac embarrassment, and may do ordinary work, "even when this necessitates going up and down stairs." This means very perfect compensation, which certainly, in our experience, may be developed *pari passu* with the narrowing of the orifice, and be maintained for years. Dr. Flint refers to the long tolerance of this form, and speaks of cases which have been under his observation for from ten to fifteen years. As he well remarks, such facts must be taken into account with reference to the prognosis, and we still are inclined to follow Peacock and some of the older writers, and put mitral incompetency next in order of gravity to aortic regurgitation.

To the interesting questions in diagnosis contained in these papers we shall return on another occasion.

IODOL.

The recent discovery of a substance to which has been arbitrarily given the name of iodol, and its application as an antiseptic to wounds, have been mentioned in The News. Desirous of knowing whether iodol had unequivocal germicidal power, and, having that power, how great it was, we applied to Dr. Sternberg to test these points. He very kindly has made this investigation, and we are sorry to say that the results are negative. He states that a saturated aqueous solution was added to an equal quantity of gelatine solution, and put in a warm place; at the end of twenty-four hours the mixture was swarming with the bacteria of putrefaction. The experiment was repeated with urine, and the result was similar. He then added a considerable quantity of the powder to fresh urine, in a test-tube, and after shaking the mixture well allowed the powder to subside, and then added a drop of broken-down urine. At the end of twenty-four hours the urine in the test-tube had undergone puterfactive decomposition, and was swarming with microörganisms. In addition to the insolubility of iodol as thus shown, Dr. Sternberg suggests that

as a powder in direct contact with a granulating surface, iodol might have a certain antiseptic value, or possibly in the presence of a discharge from a suppurating wound it would be slowly decomposed, and iodine set free, but this can only be determined by clinical experiment.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eightieth Annual Meeting, held in the City Hall, Albany, February 2, 3, and 4, 1886.

(By Telegraph from our Special Reporter.)

TUESDAY, FEBRUARY 2.—FIRST DAY.

MORNING SESSION.

THE Society was called to order at 10 o'clock by THE PRESIDENT, DR. ALBERT VANDER VEER, of Albany, who, after prayer by the Rev. Walter D. Nicholas, delivered

THE INAUGURAL ADDRESS.

He congratulated the Society on its excellent financial condition. He suggested that the By-laws be changed, under the authority given by a recent Act of Legislature, so that the number of delegates and permanent members from the county societies be increased at least fourfold. He recommended that in every alternate year the annual meeting be held in some other part of the State than Albany, believing that this would create local interests which would eventually lead to mutual good.

In reference to the International Medical Congress, he said: In the time that has elapsed since we last gathered here, the medical profession of this country has been called upon to pass through, it is to be hoped, its greatest period of humiliation. We that were present remember well the pleasure that was afforded when Dr. J. S. Billings, at Copenhagen, in the name of the profession of the United States, extended the invitation to the International Medical Congress to meet in 1887 in America, and rejoiced to see that invitation so cordially accepted. Alas, how soon were our hopes and delights dashed away from us, when the American Medical Association at the meeting in New Orleans saw fit to undo all the good work that the original committee of seven had accomplished, and under the plea of geographical distribution enlarged its committee to forty-five members, doing it so cunningly as to drop the names of all who had ever been independent and fearless enough to express in an honest and manly way their convictions on the subject of all codes.

The result of that action is well known to us all. The great solicitude for the success of the Congress manifested by those who manipulated that movement has produced its effects, as was expected by the better judgment of men whom they would not heed.

Many resignations have resulted, until at last it becomes a grave question as to whether the Congress will meet here at all in 1887, and if so, the success of the meeting appears doubtful. I well remember having conversations with many of the foreign members in regard to the meeting of 1887, and it was well understood by them that all questions relating to codes and medical politics were to be left out, and only on such condition would they accept. As one has so well remarked, "The way is long and the fear of the sea is strong," and there must be unity and peace and great attractions to bring them from the mother country.

Among the names so dropped are those of many of the very men about whom foreign physicians are the first to inquire, and with whom they are best acquainted, not only through their writings but by personal contact. In speaking of this uncalled for action on the part of the American Medical Association most of the foreign journals have condemned it, but the remark of one, especially, is so true that I make the quotation: "The American medical profession is not so rich that it can afford to play all Europe with only pawns on its side of the board." Whether, as has been suggested, it is possible for the American Medical Association to accept the advice given by the best men of Philadelphia, and retrace its steps, is a matter of grave doubt. Time is passing rapidly, and what is to be done must be done quickly.

How different the action at New Orleans from the sentiment of that great scholar, Prof. Virchow, as embodied in his last address before the Congress of German Surgeons. While dwelling upon the subject, he states tersely that no body of scientific men who are honest and true need anything on the subject of medical ethics to guide them. No codes—for no man has ever yet been made by such restrictions to act the part of a gentleman who would not naturally have done so without them.

It is a source of gratification to us as a Society to witness the good results now being obtained by our position of a few years since, regarding the proper understanding of the Code of Ethics. The Society which then so hastily and promptly refused our delegates admission to its meeting at St. Louis, has since had its conscience disturbed, and at its last convention in New Orleans gave an interpretation of certain portions of its Code, which is surely in the right direction, differing but little in reality from our own view of the question. I have no love for quarrels and would say, let the American Medical Association alone in its view of Codes, but when it attempts, as it has, first to refuse us recognition in a Congress in which we have as much right to be represented as they, and then, at last, when the pressure of professional opinion becomes too great, offers us membership but no official standing, it is time we protest. An editorial in THE PHILADELPHIA MEDICAL NEWS of January 30th, entitled "The Congress Controversy and the Code," is so fair and candid in its statements as to the situation, that I would earnestly refer its perusal to every honest-hearted member of the profession in this country.

THE PRESIDENT then announced the serious illness of the VICE-PRESIDENT of the Society, DR. ALFRED C. POST, of New York.

DR. VANDER POEL offered the following resolution, which was unanimously adopted:

Resolved, That this Society learns with regret of the illness of its Vice-President, Dr. Alfred C. Post, and tenders to him its earnest sympathy and sincere hope of his recovery.

THE BUSINESS COMMITTEE offered the following:

Resolved, That a committee of three be appointed by the President to consider the recommendations contained in the Inaugural Address, and report at this meeting. Adopted; and Drs. F. R. Sturgis, of New York, W. S. Ely, of Rochester, and H. R. Hopkins, of Buffalo, were announced as the committee.

The Provisional Business Committee, consisting of Drs. W. W. Potter, of Buffalo, Daniel Lewis, of New York, and A. M. Phelps, of Chateaugay, was appointed as a Permanent Business Committee.

THE COMMITTEE ON LEGISLATION

reported that a bill to establish a Board of Medical Examiners had been prepared and is now pending in the Senate and Assembly.

The following bill has been introduced and passed:

"That the Medical Society of the State of New York should have full power to elect such number of permanent, delegate or other, members as may be provided for by the Constitution or By-laws of the State Medical Society, said Medical Society of the State of New York being hereby empowered to regulate and control its own membership."

The following bill was also passed:

"That medical societies may hold real or personal property to an amount not exceeding one hundred thousand dollars, and that no member of any said society shall be assessed a greater sum than five dollars in any one year."

DR. C. L. STILES, of Oswego, reported the

HISTORY OF A CASE OF ABSCESS DISCHARGING THROUGH THE BLADDER.

F——, aged fifty-seven, married, plumber by occupation, ex-cavalryman, claimed to have received an injury in the region of the spleen by slipping from his horse during parade. At the time of accident he had pain at point of injury, and the part was tender for some time. Dr. Stiles saw him August 9, 1881, and treated him for splenitis, from which, after a time, he recovered.

In May, 1882, the feet and legs became swollen, the condition of the left limb being most marked. Urine contained albumen. He recovered after several weeks' treatment.

May 5, 1885, he was again seen, complaining of pain and tenderness in the region of the spleen, 2½ inches below and 1½ inches to left of umbilicus. Here there was an area of considerable hardness, 2½ inches in diameter and ¾ inch in thickness. This spot was not very sensitive, but it was the seat of considerable dull pain. This enlargement was noticed three months previously. On May 28th, he was almost free from pain, but the enlargement remained the same. He then returned to work. There was no evidence of fluctuation.

On October 29th, he was seized with violent attacks of colic. November 4th there were similar attacks, both relieved by a hypnotic. November 23d he was again seen, at which time the enlargement was unchanged.

On December 2d he suffered considerable pain. On the 3d the enlargement measured six by seven inches and three inches in thickness. No fluctuation could be detected. There was no rise in temperature. On the 7th, fluctuation was detected, and it was resolved to aspirate the next morning. On the 8th the enlargement had disappeared. The patient stated that the tumor was present at 4 o'clock the previous afternoon, but at 6.30 P.M., the same day, he found that it was absent. It had disappeared without his knowledge, although he was awake. There had been no inconvenience or pain produced. At 8.30 P.M. the patient passed a large quantity of dark colored urine. Later he passed a still larger quantity. Examination of the vessels containing the fluid passed showed that there was at least a quart of pus. Microscopic examination revealed the presence of abundant cholesterine crystals. For the next two days more or less pus was passed. The patient experienced no pain or inconvenience where the enlargement had been. From this time he rapidly improved, and on January 28th was at work and had been working for two weeks.

DR. J. LEONARD CORNING then read a paper on

THE CURATIVE POTENCY OF PROLONGED SLEEP.

The progress in therapeutics has undoubtedly been great of late years, but in spite of the advancement in the classification and knowledge of remedies our greatest victories are won through the coöperation of nature herself. The *vis medicatrix naturæ* remains still the factor of greatest potency in treatment; if we desire to combat disease successfully, we must lay hold upon some great law or laws of physiology and appropriate the hidden forces thus placed at our disposal to the ends of scientific therapy. One of the most brilliant, if not the most striking exemplification of the truth of the above proposition is found in the practical application of *rest* to curative ends. Unfortunately, however, there has been great confusion in the conceptions of rest heretofore prevalent. If we are asked in what manner does the brain obtain rest, we reply: through the instrumentality of the conditions collectively designated as *sleep*. Therefore, any system of cerebral rest which can lay claim to physiological consistency, must have for its corner-stone sleep. And furthermore, inasmuch as the amount of sleep is in direct proportion to the vital expenditure of the organ, we should see to it that the greater the exhaustion of the brain the greater the amount of sleep we prescribe for our patient. *Prolonged sleep may, therefore, be set down as the cardinal principle of physiological brain rest.* It must, however, be combined with systematic and scientific overfeeding, in order that repair of the exhausted brain may proceed in a physiological manner during the interval of unconscious repose.

The essential features of a scheme of brain rest then, are: (1) progressively prolonged sleep; (2) increased general and cerebral nutrition; (3) diminution of psychical irritation; (4) elimination of sensory impressions, particularly those of light and sound.

In carrying out this scheme of treatment, Dr. Corning is in the habit of secluding the subject in a darkened room, eventually for from ten to fifteen hours at a time, according to the amount of sleep which it is desired shall be had during the twenty-four hours. The amount of sleep is *progressively* increased by habit, moderate medication, and hydrotherapy; but he never resorts to forced sleep by the reckless abuse of sedatives. When the patient awakes, as is sometimes the case, two or three times during the hours set apart for rest, nourish-

ment is administered, but always in an easily digested form. The few hours of wakefulness are devoted to some form of amusement, but all forms of mental exertion are strictly prohibited.

DR. B. F. SHERMAN then reported

A CASE OF EMPYEMA,

which illustrated the result of using the aspirating apparatus and the valvular drainage tube devised by Dr. A. M. Phelps. The aspirator differs from those in ordinary use by having a third tube through which the bottle may be cleaned and the pleural cavity washed out. The aspirating needle is modified by being provided with a shield to prevent irritation of the tissues.

The patient was seen June 15th; aged nineteen, farmer, parents living and healthy. In the previous September had measles, and while convalescent, on Oct. 11th, had a severe chill followed by fever with severe pain in the right side. The pain and fever continued and the right side became swollen. On December 3d, a small opening in the sixth interspace, right side, formed, through which a large amount of pus escaped. This gave temporary relief.

When the patient came under his observation, there were profuse night sweats, great emaciation, and extreme weakness, the patient fainting during the examination. Pulse 130, respiration 40, temperature in axilla 103°. The right side of the chest was enlarged, the intercostal spaces bulging. The whole right side was flat on percussion to within one inch of the clavicle. The left side was resonant throughout. There was no sound on auscultation over the right side until the clavicle was reached. On the left side there were exaggerated respiratory murmurs.

Jan. 17th, at 10 A. M., three grains of quinine and one ounce of whiskey were given, and the aspirating needle introduced between the ninth and tenth ribs, two inches to the right of the spine, and thirty-two ounces of pus were drawn off. The pleural cavity was then washed with carbolized water, 1:80, at a temperature of 100° F. The operation was well borne. On the 18th there was only a slight discharge from the opening in front and none from that in the back. On the 21st, sixteen ounces of pus were removed. A valvular drainage tube was introduced into the posterior opening, and the anterior opening was enlarged and a rubber tube fitted with a plug was introduced. A few days later the chest was again washed out and forty ounces of pus, by actual measurement, removed. This treatment was continued until July 20th, when the tubes were removed and the openings sealed with lint saturated with compound tincture of benzoin. July 25th, the patient was discharged cured, and in August he returned to work in the harvest field.

A year later, the lung was in perfect condition, there being no deformity of the chest.

DR. WM. S. ELY, of Rochester, then read a paper on

PULMONARY GYMNASTICS.

Although it is well understood that a relation exists between chronic pulmonary disease and defective chest development, it is not the rule to recommend any special treatment for overcoming this condition. Sometimes the pulmonary capacity is deficient from lack of development, at other times it may be diminished by compression of the lung from pleuritic effusion. The object is to discover some plan of treatment which shall in the one case symmetrically increase the chest circumference, and in the other expand the compressed lung. He had been led to believe that at any age lung expansion, when deficient, could often be relatively increased by the persistent use of pulmonary gymnastics.

In ordinary respiration only a small part of the pulmonary capacity is called into play. While in quiet breathing the tidal air is stated as about twenty cubic inches, when extreme breathing is tested the complemental air is said to be equal to one hundred and ten cubic inches. The author had for years noted the undeveloped action of "extraordinary auxiliary muscles" as a result of disuse.

The process for increasing chest expansion was described as follows: The head is fixed, and the extended arms carried upward until the backs of the hands touch at the highest point over the head. The arms are next dropped to the side, and the chest-wall is subjected to a series of direct, light, percussive efforts. To be of value, these efforts must be continued for months. One hundred of these full inspirations should be taken daily. When the efforts produce coughing, pain, dizziness, or headache, they should be temporarily omitted.

The movements described have been supplemented by subjecting the distended chest to pressure by voluntary contraction of the muscles of the abdomen and chest, while the air is prevented from escaping. Like all important remedies, this may operate injuriously. Pulmonary gymnastics can be safely prescribed only by physicians possessed of correct anatomical and physiological knowledge, and competent to diagnosticate and prescribe for different forms of thoracic disease.

DR. A. M. PHELPS, of Chateaugay, had, in 1878, operated in a case of empyema and used the valvular drainage tube. This afforded not only thorough drainage, but also enabled the cavity to be completely washed out. The idea was to cause obliteration of the abscess cavity. On the one side is the rigid chest-wall, on the other, the lung capable of collapse and expansion. The tube was intended to permit the escape of air from the pleural cavity while it prevented its entrance during inspiration. He had operated on six cases, using this tube. Three had recovered. Two were cases of multilocular abscess, and one was a case of amyloid degeneration of the lung and resulted fatally.

DR. A. L. LOOMIS, of New York, considered that the length of time the lung could be compressed and yet be restored to its normal condition, depends largely on the location of the inflammatory process. If limited to the costal pleura, a long time may elapse, while if there are extensive changes in the pulmonary pleura, the lung will expand only slowly, imperfectly, and never completely.

The case described was unquestionably one of acute suppurative inflammation. In such cases the cavity may be rapidly filled with pus; this may occur in the course of twenty-four hours. In these cases the inflammation affects chiefly the costal pleura. There is, of course, more or less secondary suppurative inflammation of the pulmonary pleura. There is, however, very little interstitial change in the pleura, at least for some

time. He is satisfied if the effusion is absorbed within a month or two, and if this takes place within a week or two perfect expansion of the lung may be expected, so that, as in the case reported, it might be difficult, a year afterward, to state which side had been affected.

There can be no question that in suppurative pleurisy the pus should be removed as soon as formed. Aspiration is simply temporizing; so far as his experience goes, aspiration is worse than useless. The only proper way is to make a free opening, and, if desired, a counter-opening. If the operation is performed early, a single opening is sufficient. A drainage tube should then be introduced. If the pus has no offensive odor, he does not believe in washing out the cavity. He saw no necessity for the valvular drainage tube. The lung will expand, if it is not bound down, as soon as the fluid is removed. This is shown in cases of injury to the ribs permitting air to enter the pleural cavity. The lung will not collapse unless it is injured. In pure suppurative inflammation it is not necessary to wash out the cavity. The changes will go on rapidly and from two to six weeks will be the limit of the case if the opening is made early. This is the great point in these cases.

In regard to Dr. Ely's paper, he had paid considerable attention to the subject of pulmonary gymnastics in his own person, and had found that, unless he was in excellent physical condition, such exercise is harmful, enfeebling respiration and increasing the danger from exposure. The question of pulmonary gymnastics in pleuritic adhesions and pulmonary disease is another matter. He thought that, although much had been written on this subject, nothing satisfactory has been attained, unless it is to be found in Dr. Williams's pneumatic cabinet.

With reference to rowing and college gymnastics, he considered that the severe training and prolonged muscular effort of such sports were laying the foundation for many cases of cardiac and pulmonary disease. As a rule, college men are overtrained for boat races and other athletic sports, and he had seen phthisis develop in a large proportion of those who had been active participants in these exercises.

DR. D. B. ST. JOHN ROOSA, of New York, said that while there are cases that do not require washing out of the pleural cavity, still there are others that do require it. There are cases in which the pus is mixed with flakes that will not pass through the canula or through an opening in the chest, a resection of the ribs being required in many such instances. When there are such flakes, the pleural cavity must be washed out, no matter what the condition of the pus. In cases where the amount of pus was large, and the lung partly adherent, the discharge of pus had rapidly diminished under this treatment. The operation should be done antiseptically, a rubber drainage tube introduced, and the wound dressed with antiseptic precautions. The next dressing should not be made for three or four days. The following dressing may not be required for a week. Under such treatment the wound heals very kindly, even where resection has been done.

In reference to Dr. Ely's paper, he said that there is a class of cases in which pulmonary gymnastics are of service. These are cases in which there is premature ossification of the cartilages, especially of the upper part. This condition can be benefited by pulmonary gymnastics. In such cases there will be expansion, especially downward.

DR. FRAZIER thought that in many cases in which pulmonary gymnastics are resorted to, the lungs have reached the fullest development of which they were capable. The overstraining of lungs which are already sufficient for the needs of the system is harmful.

DR. SHERMAN said that in his case each washing out was followed by lowering of the pulse and temperature. After the second washing, the amount of pus discharged was merely nominal.

DR. F. A. CASTLE, of New York, described a simple method of pulmonary gymnastics which was suggested for the use of a boy requiring such exercise. This consisted in placing the pockets of the jacket under the arms, so that in order to get the hands into the pocket it was necessary to expand the chest. Again, in the male adult, a large proportion of the respiration is carried on by the abdominal muscles. For this reason it is desirable to avoid, as much as possible, overdistention of the stomach.

DR. ELY said that in the cases in which the measures described were employed he had seen no serious results, but he insisted that all such exercise should be under the control of a physician.

DR. HERMAN BENDELL, of Albany, read a paper on

THE TREATMENT OF AURAL POLYPI BY THE INJECTION OF CARBOLIC ACID.

The favorite method of treatment of aural polypi has been by the wire loop and the subsequent application of caustics. One objection to this treatment is the hemorrhage which may ensue. The treatment he recommended was the injection of from two to five drops of a fifty to seventy-five per cent. solution of pure carbolic acid. This coagulates the blood in the part, and causes a slough. In some cases one application is sufficient, in others the application has to be repeated. The slough should be removed before the injection is repeated. This plan of treatment is easily applied, and is not followed by excessive reaction.

DR. ROOSA then read a paper on

THE RESULTS OF THE OPERATION FOR CONVERGENT SQUINT.

(See page 141.)

He stated that the tables would appear in full in the Society's volume of *Transactions*.

DR. HARVEY JEWETT, of Canandaigua, reported a case of

SPONTANEOUS EXPULSION OF A LARGE STONE FROM THE FEMALE BLADDER.

The accretion, before it causes serious inconvenience to the patient, becomes too large to be expelled through the natural channels, and cutting or crushing is the only alternative except in a few instances in females, where the dilatation of the urethra can be effected without doing violence to the parts.

Mrs. U., aged sixty-eight years, suffered for six years with incontinence of urine. In one of the intense paroxysms of pain she expelled a calculus measuring 3¼ by 2⅞ inches in circumference, and weighing 186 grains. The use of the sound revealed another stone, which I removed with a strong pair of polypus forceps by dilating the urethra with my finger. This

stone measured 4 by 4¼ inches in circumference, and weighed 395$\frac{1}{16}$ grains, or about 6½ drachms. This was accomplished without either laceration of the parts or hemorrhage. The bladder was carefully washed out with an aqueous solution of carbolic acid. Small gravel, with mucus, continued to discharge for six days; she was then put upon use of the Buffalo Lithia Water from the Virginia Springs. The concretions gradually diminished, and in about ten days entirely ceased, and at this date (five months after the removal of the stone) the patient is about the house, and in a comfortable condition of health.

Afternoon Session.

Dr. Hermann Bendell's paper on the

treatment of aural polypi by the injection of carbolic acid,

was then announced as being open for discussion.

Dr. T. R. Pooley, of New York, had had no experience with the remedy mentioned. The chief objection raised to the snare was the occurrence of hemorrhage. He had never seen any trouble from hemorrhage. If there is bleeding, it can be readily controlled. Two objections arise to the use of carbolic acid in the tympanic cavity. First, the possibility of the occurrence of pyæmia and septicæmia, a result of absorption by the mouths of the vessels of the bone. Second, the application may give rise to inflammation, and the periosteum may be converted into connective tissue, thus interfering with the function of the organ.

Dr. B. F. Sherman described a method which he had used with success in one case. The meatus was filled with polypi. They were dusted with tannic acid, and the operation was repeated every day or every other day; in ten days the polypi had sloughed and were removed by injection of water.

Dr. W. F. Mittendorf, of New York, claimed to have originated the carbolic acid treatment, having used it in 1881. This method he had limited to cases of large polypi present at the external meatus, and in which the patient had refused treatment with the snare. He has never seen serious results, but the application is painful and for the last few years he has resorted to the snare only.

Dr. Pomeroy said that the injection of polypi is painful and unnecessary. His method is to remove the polypi with forceps, and then touch the base with nitrate of silver fused on a probe. The canal is then filled with boracic acid. Most of the cases so treated have recovered without trouble.

Dr. George R. Fowler, of Brooklyn, read an elaborate paper on

non-union of fractures; together with a consideration of some modern methods of treatment,

at the conclusion of which he presented the following summary of his views on treatment.

1. In all cases of simple delayed union, the percussion method of Thomas, combined with an efficient retention apparatus, will be found to offer the readiest and most efficient means of bringing about union, provided this does not depend upon some dyscrasia. In cases of fibrous union, benefit may also be expected from this plan, provided absorption and attenuation of the ends of the fragments, or eburnation, have not taken place.

2. Brainard's method of drilling the fragments, and this failing, freshening the ends of the bones and uniting the periosteum by either the method of Jurdain or Rydygier, combined or otherwise, according to the exigencies of the case, with wire suture of the ends of the fragments, should take the place of the old Dieffenbach operation. This should be done with a modified antiseptic procedure, and is applicable in cases in which the percussion method of Thomas has failed because of delay in instituting early treatment, and in pseudarthrosis.

3. Cases in which it is found impossible, because of excessive loss of bone substance, to unite the periosteum by sutures or to wire together the ends of the bones, should be treated by bone transplantation, under antiseptic precautions, either by the method of MacEwen, or that of von Nussbaum.

The following gentlemen were then introduced as

delegates from the canada medical association:

Drs. T. J. Allen, Wm. Gardner, and James Stewart, all of Montreal.

the committee on prize essay

reported that only one paper had been presented. It was on drug eruptions. While a creditable production, the Committee considered that it did not represent sufficient original research to merit the prize.

Dr. Porter, from the

committee on by laws,

offered the following, which was adopted:

Resolved, That the following be added to Article I., Section 5, of the By-laws:

"All persons now eligible, and who have not been nominated as permanent members, shall inform the Secretary of this Society of their desire in this regard."

Dr. A. Hadden, of New York, then read a paper on

rheumatic affections of the joints.

He claimed that rheumatoid osteo-arthritis, often called rheumatic gout, is a disease distinct from either rheumatism or gout, and that the pathological changes are in the osseous structure of the joints. He held that the disease attacks persons who live chiefly on amylaceous and saccharine foods; and he stated that a similar disease, called "bone spavin," attacks the horse and other graminivorous beasts, while in all carnivorous animals and in birds no such disease is known. In the treatment of this disease, therefore, he recommended the substitution of nitrogenous for amylaceous and saccharine foods, and by this method he has obtained, clinically, the best results.

Dr. T. R. Pooley, of New York, reported

a case of tumor of the maxillary antrum and orbit,

the history of which will be published in full in an early number of The Medical News.

Dr. E. F. Brush, of Mount Vernon, in a paper on

infant feeding,

pointed out some simple methods of feeding an infant when it has been deprived of the breast. He urged the

claims of simple foods in preference to the so-called "patent foods," the composition of which is often unknown; he examined the constitution of the once famous "Liebig's Food for Infants," and of another popular food, and indicated the dangerous amount of alkali contained in them, citing Dr. Jacobi's warning that "we are not very careful in doses of alkali in general," and Dr. Stillé's remarks that alkaline treatment "lessens the amount of fibrin in the blood." He showed by the figures furnished by one of the advocates of peptonized food that the results of such feeding are not satisfactory.

Proceeding then to the immediate subject of his paper, he stated that one of the greatest elements of failure in the artificial feeding of infants is the desire to give *one* sort of food alone under all circumstances, and hence the prescription of patent foods. He advised, on the contrary, the preparation of foods from simple articles within reach to meet the requirements of each case as they arise. When there is failure with food thus prepared, the physician has at least a knowledge of the cause of failure.

Commencing this with the child at birth, Dr. Brush gave his formula for the best substitute for colostrum, and his further treatment if the cathartic effect is either excessive or defective. He then discussed the question, What is the best staple food? He answered unhesitatingly "cow's milk," which, however, is subject to many conditions that render it unfit, unless due care is exercised. In 1879 Dr. Brush had pointed out the difference between the milk of the ruminant and non-ruminant animals, as regards, particularly, the quantity and quality of the casein contained in them, and the difficulty experienced by the infant in digesting a milk intended for the calf. When an infant vomits a hard curd, the indications are that the milk must either be prevented from coagulating in the stomach, or coagulated and broken up before entering the stomach. He showed that it is unadvisable to use alkalies to overcome the tendency to souring in the stomach, and therefore preferred the latter treatment of coagulating and breaking up the milk before feeding it. In other cases, he recommended the addition of lime-water as the safest agent, as it does not, like other alkalies, keep the stomach in an alkaline condition, nor cause an acid condition of the intestines. In case of diarrhœa in children fed on milk, the indications are to stop the milk immediately. The milk is the cause of the trouble, and the milk is rendered unfit by the physical condition of the cow, such as œstrum, pregnancy, poisonous herbs, cruel treatment, and the like, to all of which sources many cases of diarrhœa in infants can be traced. In these cases of diarrhœa he recommended oatmeal-water, which his analysis convinced him is somewhat similar in composition to milk. He insisted on the necessity of the medical attendant himself preparing and teaching the preparation of these simple foods. In all cases, however, the child should be put back on its ordinary milk diet as soon as possible.

As regards the kind of cow best adapted to supply milk, Dr. Brush prefers the common red cow to the Jersey or fancy breeds. The latter are of a tubercular tendency, the fat in the milk is not sufficiently emulsified, and they are of higher nervous temperament, while the common cow, ordinarily, is gentle and a good feeder. She should always be stallfed, as in hay even the poisonous weeds lose their evil properties by volatilization of the poisonous principle. When milk is bought, that of one cow should always be avoided, as its composition is never uniform.

In cases of constipation, raw malt-water, carefully prepared, as a dilutant of the milk, is efficacious. In acute dysentery raw beef solution is to be recommended. In all cases of dysentery the food of the infant should be warm.

DR. A. JACOBI, of New York, referred to the fact that the difficulty with cow's milk is that it coagulates in hard curd. One method of overcoming this difficulty is that which he had adopted years ago. This consists in taking half a drachm of dilute muriatic acid, adding it to a pint of water, then adding this to a quart of raw milk, and boiling the mixture. This will keep a long time; and when it coagulates, it does so in small curds. This is well relished by healthy children, and also by children with gastric trouble. It is also of service in adults.

DR. JACOBI then read a paper on

PAPAIN OR PAPAYOTIN.

After referring to the chemistry of this substance, which is obtained by adding alcohol to the juice of the papaw plant, the physiological action was described. Its therapeutic effects were next considered. It has been found innocuous when taken internally; but when injected subcutaneously, it is followed by dangerous symptoms of paralysis of the heart and nervous system. Its effect has been compared to that of pepsin and pancreatin, with this exception, that it is effective in smaller doses. It is useful in alimentation.

Diphtheritic membranes are dissolved by it in a few hours. Several cases of diphtheritic deposit were described as showing the effects of this drug, one part to four of water and four of glycerine. In these cases the membrane was softened and dissolved, and disappeared within forty-eight hours. He exhibited specimens of egg, meat, and cheese digested by a solution of papayotin of the strength of 1 to 250.

DR. A. L. LOOMIS, of New York, then read a paper on

GENERAL ARTERIO-CAPILLARY FIBROSIS; ITS RELATION TO CARDIAC AND RENAL DISEASE,

which will appear in full at an early date in THE MEDICAL NEWS.

DR. H. R. HOPKINS, of Buffalo, has been working with the sphygmograph for a number of years. He has found high arterial tension in a number of cases as a functional disturbance. He has also seen high arterial tension precede for years the occurrence of albuminuria. In three instances he has seen high arterial tension in apparently healthy individuals followed in from six to eighteen months by Bright's disease. High arterial tension is readily diagnosticated by the methods of examining the pulse in vogue one hundred years ago.

DR. H. R. HOPKINS then presented a paper on

ULCERATIVE ENDOCARDITIS,

in which he referred to the labors of Osler and Rosenstein. The seat of this affection is, in the majority of cases, on the left side of the heart. It occurs at the seat

of impact of the valves. The disease may be primary or intercurrent. The primary cases are rare. The intercurrent affection occurs more particularly after scarlet fever, pneumonia, and pyæmia. When the disease results from pyæmia, particularly puerperal pyæmia, the location is likely to be on the right side of the heart, and the emboli are found in the lungs.

There is great difficulty in the recognition of the disease. It may be divided into certain types. A large number of cases are diagnosticated as typhoid fever. The pyrexia, however, differs from that of typhoid fever. Rigors are more common, and sweats are more profuse. A second type is the pyæmic. Here there are rigors, profuse sweating, vomiting, jaundice, and sweet breath.

The symptoms referable to the heart are often absent. The symptoms referable to the brain are hemiplegia, aphasia, unconsciousness, strabismus, delirium, and convulsive movements. Symptoms affecting the skin are profuse sweating, occasionally jaundice, and usually an eruption petechial in character. The urine is frequently albuminous. The disease is generally attributed to the presence of a microbe which is found in the diseased spots and in the emboli. Illustrative cases coming under the author's observation were then narrated.

Dr. Loomis stated that he had met with ulcerative endocarditis under three conditions: First, in rheumatic endocarditis of an exudative character, in debilitated and especially alcoholic subjects; second, in old valvular lesions; third, in acute cases of infectious endocarditis.

In regard to diagnosis, when a physician has seen one or two cases and is on his guard, the diagnosis is made without much difficulty. If the heart be watched, although there may be no murmur, there will be a peculiar action which he had never seen in any other condition. It seems as though the heart were stimulated to beat wildly. He had noticed this before the appearance of the murmur. After the murmur and the emboli appear, there is no difficulty.

Dr. Willis E. Ford, of Utica, then read a paper on

THE EARLY MANAGEMENT OF CASES OF MENTAL DEPRESSION.

He thought that in the majority of cases a period of depression precedes the development of insanity and that many cases of grave insanity might be prevented by proper treatment. The cases may be divided into two classes: those in which there is intellectual perversion, and those in which the emotions are alone disturbed and there is no fixed delusion. In cases where the physician cannot secure the confidence of the patient, where there is a suicidal tendency requiring constant watching, and where careful attention cannot be had at home, the patient had better be removed to an asylum. Cases of mental depression, where the emotions are alone affected, where there are no delusions, are improved by diversion and by travel, and appropriate medical treatment. In some cases of sudden onset of melancholia, treatment by sedatives has been effective.

Dr. J. M. Bigelow, of Albany, then presented some

HINTS ON THE TREATMENT OF DIPHTHERIA.

He advocated the use of tincture of chloride of iron in fifteen drop doses with glycerine and water, muriate of pilocarpin in one-twentieth of a grain doses every two hours, and twenty minutes later two or three tablespoonfuls of whiskey—the mouth to be cleansed with a two per cent. solution of carbolic acid, and a spray of lactic acid to be also employed. This treatment has been followed by satisfactory results in his practice.

Evening Session.

Mr. Lawson Tait, of Birmingham, forwarded a paper on

METHODS OF DIAGNOSIS,

which was then read. He maintained that the speculum and the sound, as means of diagnosis, have been productive of uniformly more harm than good. That a blennorrhagic discharge from the vagina of any patient requires the introduction of a speculum, is one of the stock beliefs of the great bulk of general practitioners, but it is certain that nothing of the kind is requisite and a very large amount of mischief, there can be no doubt, has been produced by this belief. It is not at all an unusual thing for him, on taking part in a consultation with the family physician concerning some such case, to be told by him that he very much regretted that he had not made an examination with the speculum. Others have told him that they made the said examination, and when asked what they saw, or what they did, the answers usually given are that they did nothing, they merely made the examination; that is to say, they passed the instrument and with that proceeding were perfectly satisfied, evidently under the belief that the passage of the speculum was quite as much a curative agent as a method of diagnosis. Similarly with the sound, he had heard many practitioners tell of their experience with the sound, or rather their want of it, and he judged that they looked upon it as a sort of magical charm, the introduction of which into the uterus was to achieve unmeasured good. As a matter of fact, the sound is one of the most dangerous instruments which ever was invented for the treatment of human suffering, and in his own practice obtains hardly any employment at all.

There is a story which is told against himself by some of his colleagues which he never hesitates to repeat, because it is the kind of accident which is liable to occur to any one, and fortunately the only one of its kind which ever happened to him. It conveyed a lesson of which at the time he stood much in need, and from which warning may be taken with advantage. Many years ago he was asked by the surgeon of a large general hospital to give his opinion on the case of a young woman, who had been in the hospital for some months suffering from a pelvic tumor which seemed to threaten her life. She was hectic, suffering, and very ill. The tumor on one side of the pelvis was apparently quite fixed, and he expressed the opinion that it was a collection of matter, but in what position he could not say unless she would allow him to make use of the uterine sound. His surgical friend told him he could do exactly what he thought proper. He had asked for his opinion as a specialist and he would not interfere with any steps he thought fit to take for the purpose of furnishing him with that opinion. Mr. Tait immediately proceeded to use the sound and came, quite erroneously, to the conclusion that the patient was suffering from a parametric abscess. The sound passed, as he thought, into an empty uterus, fixed toward the right side, the uterus

being of normal length. Within twenty-four hours the patient miscarried of a fourth-month fœtus, and this ended all her sufferings. She speedily recovered and left the hospital cured in a way which nobody expected, and which certainly he did not intend. All such accidents have by no means so happy an ending as this had, and their number is immense. But few months pass without his hearing of a case in which some kind of mischief has been done in this way.

One of the most important methods of diagnosis in abdominal disease, and the first to be considered in examining any case, is inspection. A careful examination, by the eye, of the contour of an abdomen when the patient is lying on her back, with the walls of the abdomen perfectly flaccid, will reveal a good deal to the experienced practitioner. A completely and uniformly distended abdomen may mean that the patient is suffering from peritonitis, intestinal obstruction, ascitic effusion, a parovarian tumor, an ovarian tumor, a large myoma of the uterus, or pregnancy. The process of discriminating between these various conditions may very rapidly be completed by one who is accustomed to deal with them. Thus peritonitis may be at once detected or eliminated by the presence or absence of the short and rapid pectoral breathing, which shows that the patient is loath to use her diaphragm. In fact, by this alone, and without almost any further inquiry, he has satisfied himself as to the nature of the case by a single glance. Ascitic effusion, on the other hand, is revealed at once by the absence of the pectoral breathing, by the greater flattening of the distention, by its tendency to assume a pyriform shape, the broadest diameter just above the pelvis, by the thickening of the walls due to anasarcous effusion, and the presence of white lines in the skin of the flanks. If the crest of the ilium sticks out under stretched skin, the diagnosis is again almost complete without further inquiry. If, on the other hand, these subsidiary features are absent, and there be a uniform and complete distention, two conditions widely distinct may be suspected. These are parovarian cyst and hydramnios; and here, again, some very curious mistakes have come under his notice, some of which have had very ghastly results. Parovarian cysts after labor sometimes grow with astonishing rapidity. Hydramnios always occurs with twin pregnancies, and generally in unmarried women, who are, of course, disposed to conceal their condition, and mere inspection cannot be depended upon to discriminate these cases.

But inspection will help us very largely to detect pregnancy and myoma, for in these cases the distention is always greatest either at the middle of the tumor or at its upper part, differing in this way completely from ascitic distention; and here one of the most important agents in the diagnosis of abdominal diseases, palpation, comes at once to our assistance, and to the skilled fingers it ought not to take more than a few seconds to discriminate between any or all of these conditions. The percussion note, which is uniform in a case of peritonitis, will easily determine the condition which is present. One or two delicate touches of the fingers of one hand whilst the fingers of the other lie with the most gentle lightness on the other side of the abdomen, will determine the presence of fluid, and it is in this method of palpation that the skill of the practitioner at once becomes visible. The inexperienced hands press firmly upon the walls and may be seen to move to and fro in an aimless fashion as though they were rocking a cradle. The gentlest and tenderest touch alone will reveal what is required. Measurements of the different diameters of the abdomen will teach in a few seconds the leading features which are present: first, that there is fluid; secondly, that it is, or is not, near the surface, being contained, or not, within a thin-walled cyst; thirdly, that there is one cavity, or not; fourthly, the probable character which it presents. The wave excited by gentle tapping is retarded or urged on by the more or less gelatinous nature of the fluid. All these conclusions are indicated with the utmost rapidity to the skilled fingers, and it is absolutely impossible to teach how this can be, save by the constant practice of the pupil. The parovarian cyst may be diagnosticated entirely from one condition, that is, hydramnios, partly by its thin walls and partly by the fact to which he has alluded, that hydramnios is very easily detected. Ascitic fluid is revealed in the same way, and by the additional fact that here and there we get tympanitic percussion notes.

The large uterine myoma is defined by its firm sense of resistance and its uniform feel and pseudo-fluctuation, also by the fact that it has a smaller diameter at the base than at the middle or upper part. Pregnancy, the rock ahead to inexperienced practitioners, can be infallibly revealed by palpation. First of all, there is fluctuation due to the liquor amnii, and it can be easily detected, and this declares the cystic nature of the mass. If the hand be made to lie gently on the parietes for a few minutes a rhythmical contraction of the uterus, by which at one time it is hard as a cricket ball and at another soft as a cushion, will become perfectly apparent, and this is as infinitely more certain sign than the sound of the fœtal heart or placental bruit. The fœtal heart is a sound which may guide and sustain the practitioner in his conclusions, but it is so easily imitated by intestinal noises, and often so difficult to find, that it is not to be depended upon with certainty. The placental souffle is probably more easily recognized than the fœtal sounds, but placental sounds are very often, in rapidly growing tumors of the uterus, so completely imitated that there is always a certain amount of doubt connected with them. But the relaxation and contraction of the uterus in pregnancy are points in diagnosis which, when once made apparent, can never be mistaken for anything else.

Dr. W. Gill Wylie then read a paper on

THE DISEASES OF THE FALLOPIAN TUBES,

which will appear in full in an early issue of The Medical News.

Dr. Mundé, of New York, said that, as a rule, he agreed with the author of the paper. Mr. Tait had demonstrated that in his hands exploratory incision and laparotomy are comparatively safe procedures, but to inculcate the idea in the minds of general practitioners that the operation is unattended with danger is going too far. The operation of abdominal section will always be a dangerous one. So long as it remains a capital operation, it should not be lightly performed for the purpose of diagnosis when we have the power to make the diagnosis without it.

Mr. Tait had stated that bimanual palpation can be made with the patient on her back as well as when she is on her side. When the patient lies on her side all the movable organs will fall to the side, and the results obtained will not be correct. He did not approve of that method of making bimanual palpation.

In pyosalpinx there are two methods of operating. In movable pyosalpinx he thought laparotomy should be performed. When the dilated tube, filled with pus, is adherent to Douglas's pouch the diagnosis should be made by aspiration through the vagina. The tube should then be opened and a drainage tube introduced. In hydrosalpinx, he thought that no severe operation should be resorted to.

In those cases of muscular hypertrophy of the tube due to stenosis or atresia, the result of catarrh of its lining membrane, it is sometimes difficult to decide whether to operate or not. In some cases the patients complain greatly, are practically bedridden, and require operation. In other cases the pain is experienced only at the menstrual period, and these cases do not always require operation.

THE PRESIDENT, DR. VANDER VEER, believed that Mr. Tait's success was to be attributed to his experience, as he devoted his whole time to the subject of abdominal surgery. He did not think that the profession in this country, or in England, fully appreciate what is understood by the Tait operation. Mr. Tait holds that if any portion of the ovary or tube is diseased, the whole of the uterine appendages should be removed. He had seen cases illustrating the truth of this principle. He did not think that the position with the patient on the back is a good one for bimanual examination. With reference to the case described by Dr. Wylie, in which peritonitis ensued, Mr. Tait lays great stress upon such cases, and would probably operate, even if the patient seemed almost moribund. He insists on the thorough washing out of the abdominal cavity. This is one of his strong points.

DR. HAILES, of Albany, asked opinion in regard to the following case: A young woman, twenty-eight years of age, had died as the result of an injury to the leg, and an autopsy was made. An interesting condition was found: the uterus had been pregnant, the left ovary was in a state of cystic degeneration, and the size of a lemon. The right ovary was also diseased, and presented a thin-walled transparent tumor. During the examination the cyst ruptured. The question suggested was, what would be the effect of such rupture during operation.

DR. WYLIE said that three of the cases described were distinct cases of pelvic abscess. Some of them might have been opened from the vagina, but he felt it his duty to perform laparotomy, for there was an abscess above, which could not have been opened from the vagina. Dr. Hailes's case seems to have been one of cystic degeneration frequently met with in hysteria and hystero-epilepsy. These cysts rupture without producing serious results. He had ruptured them intentionally without harm resulting.

DR. P. R. FURBECK, of Gloversville, read a paper entitled *The Establishment of a State Board of Medical Examiners*. It was referred to the Committee on Legislation.

DR. J. A. S. GRANT-BEY, of Paris, France, communicated a paper

ON CHOLERA.

He held that when cholera appears in Egypt, it is the result of the germ having been imported, and that it is a specific disease characterized by violent vomiting and purging, with rice-water stools, cramps, prostration, collapse, suppression of urine, albuminuria, etc., tending to run a rapidly fatal course. It is essentially different from sporadic cholera, the difference being characterized by the presence of a germ (comma bacillus) in the former and its absence in the latter. Asiatic cholera is transmissible because this germ is a living organism, and transmissible in a live state. Much may be done to prevent its spread. Every epidemic rages amid filth. Personal cleanliness and house cleanliness are of vital importance. Nuisances of every description should be abated. Rooms, cellars, and water-closets should be whitewashed; the crowding of sleeping apartments should be avoided; thorough ventilation must be allowed. Food or drink injurious at ordinary times is doubly injurious in cholera season. Impure water is the most convenient vehicle for the cholera germ. To be quite safe, it should be boiled and carefully cooled before being drunk. Partially ripe fruit should be cooked before being eaten, and ripe fruit eaten raw should be washed before it is taken into the mouth. Temperance in eating, drinking, and exercise should be recommended. Thorough disinfection of the apartment in which a choleraic case exists, of the person of the patient, of the matter vomited and that discharged from the bowels, of all materials that have come in contact with these matters, and of the persons and clothing of the attendants, is of vital importance.

The best disinfectant is plenty of pure air. The germ of cholera becomes entirely inert in the open air, and this is the reason why it always travels along the routes of communication whatever the direction of the wind may be. Heat is a valuable disinfectant. Hence, if our food is well cooked and our drink well boiled, the danger of getting cholera through these is removed; and it is well to understand that the evidence in favor of the communicability of cholera by means of water and food contaminated with the cholera germ is now overwhelming. In addition to pure air and heat, sulphurous acid fumes, chlorine gas, and permanganate of potassa may be mentioned as valuable disinfectants.

At the commencement of an epidemic, cholera manifests itself without a premonitory symptom, and death takes place in a very few hours; but ordinarily there is a premonitory diarrhœa, the stools being copious and watery, followed by great prostration of strength.

If judiciously treated, many persons recover from this, *the first stage* of cholera; but, if neglected, the disease grows rapidly worse; the stools, becoming more frequent, have the appearance of rice-water; vomiting now commences, and prostration is complete. There are intense thirst and severe cramps in the limbs, and the voice becomes husky and the pulse imperceptible. The duration of this, *the second stage* is very uncertain, but the weaker the pulse becomes the nearer the patient is to *the third stage*, or that of collapse, from which few recover. Those who recover, however, often succumb afterward to some of the complications set up

by the primary disease, such as suppression of urine, inflammation of stomach and bowels, etc.

In the first stage of epidemic cholera we endeavor to stop the purging, and here opium is our sheet-anchor. The best way of exhibiting it in cholera is the preparation known by the name "Tincture Chloroformi cum Opio (Kirby)" (R. Tinct. opii, ℥ss; spt. camphoræ, ℥ss; tinct. capsici, ℥ss; chloroformi, ℥iss; spt. vini rect. ad. ℥iiss. M.), of which twenty drops for an adult and five drops for a child should be given in half a wineglassful of water or chamomile tea every hour or two till diarrhœa ceases, and no nourishment given except beef-tea or chicken soup and rice. If the diarrhœa is not checked and vomiting commences, the "Anticholerique selon Pasteur" (R. Hydrarg. bichlror., gr. ij; spt. chloroformi, ℥x; spt. camphoræ, ℥x; tinct. lavand. co., ℥ss; spt. vini rect., ad. ℥ij. M.) should be used and the other medicine omitted. This "Antichlorique" contains the ingredients for killing the germ of the disease and for stopping the diarrhœa, vomiting, and cramps, while it stimulates the heart and favors a general reaction. It is very hot and biting, and has, therefore, to be mixed with a sufficient quantity of water or chamomile tea to make it palatable. The dose is a teaspoonful for an adult and a half a teaspoonful for a child or young person, in a wineglassful of water, every quarter of an hour, every half hour, every hour, and so on according to the urgency of the symptoms.

Mustard poultices may now be applied over the abdomen, and mustard with a little olive oil should be rubbed up and down over the cramped muscles. Thirst should be assuaged by means of ice, which is very agreeable to the patient, while giving water to drink *ad libitum* would only hasten death. The ice should not be stinted, but the patient allowed to eat as much as he chooses; he will frequently devour a pound or two of ice in the course of an hour. In the treatment of cholera, there can be no question about the value of ice. The patient should be prohibited from drinking water, except that from the melting of the ice or that in which he takes his medicine. Warm chamomile tea, however, may be given in small quantities, from time to time, to soothe the stomach and allay vomiting.

In the stage of collapse heat and friction may be applied with advantage to the surface of the body, and the patient given some chamomile tea, or even iced water, to drink. Wine and stimulants at this stage do harm instead of good; therefore, they must on no account be given.

When reaction comes on, guard against doing too much. Iced milk or arrowroot or weak beef-tea may be administered by the rectum every six hours, in case of great prostration. Many nostrums have been put forward for the cure of cholera, and in 1865 they were all faithfully tried and found wanting.

In conclusion, Dr. Grant's opinions about cholera may be briefly stated thus: Cholera is caused by a living organism the habitat of which is the Delta of the Ganges, just as the habitat of the hippopotamus is the upper Nile. All attempts on the part of this organism to form new habitats have failed; at least so far as Egypt, Europe, and America are concerned. Were a hippopotamus met with in the Hudson River, it would at once be concluded that it had come from its well-known habitat or had escaped from a menagerie that had originally got it from the Nile. As our great scientists, Tyndall and Huxley, have renounced the idea of spontaneous generation, the same reasoning that is applicable to the hippopotamus is equally applicable to the lowest living organism whether animal or vegetable. The cholera germ, being a living organism, is transmissible in a live state. In Dr. Grant's opinion, this organism has different stages of development, and it is not capable of inducing a choleraic attack except at a certain stage of its existence. Hence recent choleraic stools are not contagious, but stale ones are highly so. Epidemic cholera differs from sporadic cholera in many respects:

1st. The difference implied in the names.

2d. In sporadic cholera we have generally a history of indigestion occurring in a spell of warm weather.

In epidemic cholera, on the other hand, we have no such clew to the malady; but on tracing it, find that it has come from a port or frontier town that has been in communication with an infected district, and on further inquiry it will be found that every epidemic of this disease, outside India, has been preceded by a recrudescence of it in India.

3d. Sporadic cholera is more a summer disease, appearing when fruit is ripe, while season has little or no influence upon epidemic cholera.

4th. Sporadic cholera, although often attended by partial suppression of the urine, is not accompanied by albuminuria,

5th. Sporadic cholera is not followed by a typhoid state, as is epidemic cholera,

6th. In sporadic cholera there is not the comma-bacillus of Koch. Whether this organism is the cause or effect of epidemic cholera, it is at least diagnostic of it, and if we can prevent its development we shall extinguish the disease which its presence indicates. If we were to prevent the thunderstorm the milk would not sour, but let the thunderstorm work its worst, and ply our knowledge to prevent the development of the bacterium lactis, and when we have achieved that, we shall be able to preserve our milk from souring, even in unfavorable electrical conditions, if the bacterium is the immediate cause of the souring.

7th. In sporadic cholera followed by death the mucous membrane of the bowel shows that inflammatory action has commenced at the stomach and extended thence down into the bowel.

In dry cholera, on the other hand, followed by death, the mucous membrane of the lower part of ileum for about two feet above the ileo-cæcal valve is found particularly congested, almost pink in color, while the rest of the mucous membrane may be perfectly normal in appearance.

8th. Sporadic cholera is not in any sense a contagious disease, and is not, therefore, imported into the locality where it exist, but takes its origin on the spot from the causes alluded to above.

Epidemic cholera, on the other hand, is always brought to a non-infected locality by cholera patients, or by articles that have been soiled with the dejections of cholera patients.

9th. Epidemic cholera is very fatal, while sporadic cholera is not.

Dr. Grant's explanation of the cause of death in epidemic cholera is somewhat as follows:

Immediately above the ileo-cæcal valve there is a

decided slowing of the downward movement of the contents of the small intestine, and a partial check at the valve itself, by ascent of fecal matter from the cæcum to the ascending colon. This affords time for the development and multiplication of the cholera bacillus, the spores of which had been swallowed and had retained their vitality, while the swallowed bacilli themselves had perished in the acid juice of the stomach. Be this as it may, it has been demonstrated that at the ileocæcal valve, and for some little distance above it, is found the chief seat of the cholera bacillus.

At this particular part of the bowel absorption is more active than at any other part, proving that here must be a larger supply of the delicate nerve network that exists in the wall of the intestine. The facility afforded at this part for the absorption of ingredients that had been left unabsorbed by the upper part of the bowel, no doubt also favors the penetration of the cholera bacillus. A mechanical irritation, therefore, of the fine layers of nerve network, is set up by this organism, the result being collapse and death, such as we have in fatal strangulated hernia. The secretion of a special poison, or the production of a ptomaine by this bacillus, is not, in his opinion, necessary to account for death.

The ganglionic system of nerves is simply disturbed through the local irritation caused by the active presence of this organism. The control over nutrition is lost, the doors are thrown wide open for exosmosis, and thus endosmosis is prevented. All the organs immediately under the control of the sympathetic system are nearly paralyzed in their action, or very much disturbed. The blood, from loss of serum, becomes thick and unfit for circulation, and the heart refuses to act, and, therefore, ceases to beat.

Wednesday, February 3.—Second Day.

Morning Session.

The Society was called to order at 10 A.M.

The Committee on By-laws reported against the approval of the by-law of the New York County Society providing for

EXPULSION FOR NON-PAYMENT OF DUES.

A motion to lay on the table having been made and lost, the report was accepted.

Dr. Derby, on behalf of the committee to consider the question of the existence of

CONTAGIOUS EYE TROUBLE IN CHILDREN'S ASYLUMS

of New York and its vicinity, reported that careful examination showed that thirty-two per cent. suffered from such troubles, and presented a bill providing that every incorporated institution for the care of children shall have attached to it a regular physician, who shall carefully examine all children applying for admission, and give a certificate stating whether the applicant is suffering from any infectious or contagious disease, especially of the skin or eyes. Any such child shall not be allowed to enter the institution, but shall be confined in an infirmary. It is also made the duty of the physician in attendance to give notice in writing, to the proper authorities, whenever any dormitory shall be overcrowded, so that there shall be less than six hundred cubic feet to each individual.

The State Society indorsed the bill, for the purpose of aiding its introduction into the Legislature.

THE REPORT OF THE TREASURER

showed a balance of $467.00.

Dr. A. R. Simmons, of Utica, presented a paper on

ACUTE NEPHRITIS, ESPECIALLY AS FOLLOWING DIPHTHERIA.

In diphtheria, he said, nephritis results from the products of the disease within the first eight days. Irritant remedies are to be avoided; mercury must be used with care. The indications for the treatment are to relieve congestion of the Malpighian tufts, to reduce the thickened mucous membrane, and to carry off the epithelial débris. Two general plans of treatment may be pursued. One to increase the excretory action of the kidneys; the other to act on the other excretory organs, viz., bowels and skin. A combination of these methods is the best plan. Irritant diuretics and nitrogenous food should be avoided. He concluded his paper with a series of illustrative cases.

Dr. Wesley M. Carpenter, of New York, read

A CLINICAL NOTE ON ALBUMINURIA AND GLYCOSURIA,

in which he directed attention to a few clinical features present in two cases which had fallen under his observation.

Case I. was a woman, aged fifty-five, a patient of Dr. Avery, who had been in good health up to one year previously, when she noticed that on some days she passed more than the usual quantity of urine. No other symptoms were developed until it was noticed that her face was swollen under the eye; swelling of the feet soon followed, with difficulty of breathing, and Dr. Avery detected the physical signs of œdema of the lungs. The symptom for which his advice was sought, was the sudden development of difficulty in breathing. At that time the œdema of the feet and face consisted of only a puffiness about the eyes and a moderate swelling about the ankles. Dr. Avery found that the urine contained sufficient albumen to solidify nearly its entire bulk. The specific gravity was 1.010, and the quantity was diminished. Microscopical examination by Dr. Carpenter revealed casts of nearly all varieties except blood, and in very great abundance.

A full dose of elaterium was administered, which operated freely. This was followed by the use of nitroglycerine, one drop of a one per cent. solution, three times a day. The urine was examined chemically twice daily, and microscopically once a day. At the end of two days only a trace of albumen could be detected. The specific gravity was 1.017, the quantity was nearly normal, and it contained only a few casts. At the end of a week both albumen and casts had disappeared entirely. The nitroglycerine had been continued, but at the end of two weeks its administration was interrupted with intervals of three or four days, and at the end of two months the remedy was discontinued. Examination of the urine was repeated at intervals, from this time on, but with negative results.

At the end of three months it was noted that the specific gravity was above 1.020, that the quantity had increased considerably, and it was then tested with Fehling's solution and revealed distinct evidence that it

contained sugar. From that date forward, now nearly two years, the patient has exhibited some of the ordinary phenomena of diabetes mellitus, the quantity of sugar varying according to the rigidity with which the prescribed diet had been adhered to and the regularity with which the arsenite of bromine had been taken. Albumen has not reappeared in the urine, and the general condition of the patient has remained fair.

The chief points of interest in this clinical history are, first, the well-marked symptoms of kidney disease; second, their rapid disappearance under the influence of nitroglycerine; and, third, the appearance of glycosuria, which has thus far remained permanent.

Albuminuria occurs not infrequently with glycosuria. Senator has expressed the opinion that under such circumstances the albuminuria is not to be regarded as evidence of Bright's disease, and that it indicates merely a swollen and slightly granular condition of the renal epithelium. In the case reported, however, it seemed evident that changes existed in the kidneys far beyond a simple swollen condition and granular degeneration of the epithelium of the uriniferous tubules.

Another question which arises is, Did not the glycosuria precede the kidney affection? The facts that the albuminuria disappeared entirely, and that the urine has not since contained casts, favor the view that this conclusion is not unreasonable.

Case II.—In June, 1885, Dr. X. gave Dr. Carpenter an accurately recorded clinical history of his own case for one month, in which it was found that the urine contained sugar, but in general the patient had not suffered any special inconvenience on account of its presence. The interesting feature of the case pertained to the diet. The patient, immediately on discovering sugar in his urine, restricted himself to the usual diabetic diet, and the result was the prompt disappearance of sugar from the urine according to Fehling's test. The first compromise consisted in eating gluten bread, when he found that within two hours after he had taken it sugar was present in his urine. This experience agrees with that obtained by a large percentage of those who have eaten diabetic bread bought at some of the more popular establishments. From this point the patient began to experiment with reference to his diet. He soon discovered that watermelons could be taken without being followed by sugar in the urine, and he therefore ate them very freely and with evident benefit. He also learned that he could eat raw peaches without limitation and with impunity. The doctor also discovered that ingestion of any of the cereals except buckwheat was quickly followed by sugar in the urine. He has been able during the last six months to eat buckwheat cakes without detriment, but recently he has noticed that their ingestion has been followed by a slight trace of sugar in the urine.

The most noteworthy fact concerning his diet is that potatoes do not produce sugar in his urine. This article has been particularly prohibited in diabetic diet lists. Doubtless in most cases its use is detrimental. Occasionally, however, cases have been reported in which potatoes have been eaten without being followed by sugar in the urine. Why the potato starch does not produce this effect while the starch in the cereal does, is still a question. Such cases verify the statement of Pepper, that the governing principle is that starch and sugar should be excluded from the diet of diabetics, but at the same time no inflexible rule applicable to every case can be made.

This patient has used arsenite of bromine, with restricted diet, and his general condition remains good.

In connection with the examination of the urine by means of Fehling's solution, Dr. Carpenter directed special attention to an additional step in its application proposed by Seegen, of Vienna, who had described a method by which he claimed to be able to detect sugar in the urine when it could not be detected by the tests ordinarily made. The method has been revived by Dr. McBride, of New York, who was aroused to its importance by a personal interview with Seegen and by seeing it applied. The method is as follows: Take, for example, a specimen of urine from which sugar cannot be precipitated by Fehling's solution. Filter this urine through *blood charcoal* (not ordinary animal charcoal), then wash the filter with distilled water, and test the third and fourth washings with Fehling's solution, and if sugar is present it will be detected readily.

The explanation is that the urine contains certain substances which are capable of holding sugar in chemical combination, that these substances are detained in the filter, and that by repeatedly washing the filter with water they are made to release their control over the sugar and allow it to be precipitated by the copper test.

Dr. C. Wey, of Elmira, read a paper on

MEDICAL TESTIMONY AND THE HYPOTHETICAL QUESTION,

in which he deprecated the present condition of expert testimony. One expert is contradicted by another equally competent expert. The charge that medical experts are hired advocates is capable of proof. The opinions of scientific physicians are often offset by those of local physicians of less attainment. Physicians and lawyers agree that the present system should be abandoned. Dr. Wey favored the selection of an expert or board of experts by the Court or by the Governor.

A hypothetical question, he said, may be based upon acts which are entirely separated from their surroundings, giving them entirely different significance, and based upon exceptional conditions of the individual. Every one's conduct is at periods open to the danger of hypothetical questions.

Dr. B. F. Sherman said that this is a question of great importance, and one which is neglected by the profession. The expert should be free from the bias of being employed by one or other party. He should be the witness of the Court. In many questions scientific evidence is stronger than that of supposed eye-witnesses. While what Dr. Wey says is true with reference to hypothetical questions, yet the opposing counsel have an opportunity to correct any misrepresentations which may be made.

Dr. Walter B. Chase, of Brooklyn, read a paper on

ANTISEPTICS IN MIDWIFERY.

He held that vaginal injections during the progress of labor are harmful by washing away the mucus which coats the vagina, thus retarding labor and increasing the danger of laceration of the cervix. Subsequent to labor the injection is not required and may unnecessarily irritate the patient and may even enter the uterus and the peritoneal cavity. Pyæmia and septicæmia do

occur sometimes where injections are not used, but that they are the result of their omission is not proved. The conditions under which antiseptics are to be used were then stated. The pregnant woman is to avoid all contagious diseases. If exposed to them, she should immediately change her clothing and bathe herself with an antiseptic solution. The physician, if exposed, should act in the same way. Instruments are to be treated with antiseptic solutions. Antiseptic injections should not be used in normal labor until its termination. In complicated cases, maceration of the fœtus, etc., their use may be indicated. In cases of retained placenta, laceration of the cervix or perineum, injections may be required.

Dr. Lucien Howe, of Buffalo, then read a paper on *The Recording of Cases.*

Dr. E. L. Keyes, of New York, read a paper on

THE TREATMENT OF VARICOCELE AND HYDROCELE,

in which he advocated subcutaneous ligation with catgut. He uses two different forms of needle, according to the character of the cases. One has a lance-shaped point, the other a hypodermatic-needle point of the size of No. 4 catheter, French gauge. These have long eyes near their points. Thorough antiseptic precautions are employed. Ether cannot be given, as the patient must be erect. Hypodermatics of cocaine may be used. The patient stands in a good light, the veins are separated high up from the rest of the cord, and are pressed toward the thigh The needle is armed with catgut and silk loop, and thrust through from before backward between the veins and the remainder of the cord. The end of the catgut is drawn out posteriorly, and the needle is withdrawn from the posterior opening until it can be placed in front of the veins, and brought out again through the posterior opening and the catgut threaded in the loop and withdrawn. A few fibres of the dartos are included in the ligature, and are broken by drawing on the scrotum. The catgut is then tied in a triple knot. The patient is confined to his house for forty-eight hours. This operation has never been followed by any complication, and has always resulted successfully.

In the treatment of hydrocele, he highly endorsed the method of carbolic acid injection introduced by Levis, and described the method of injection which he employs. He uses a glass syringe, holding one hundred minims, and fitted with a hypodermatic needle. If the hydrocele is small, the needle of the syringe is thrust in and fluid drawn off. The syringe is then washed, the needle being left in. Pure carbolic acid deliquesced by glycerine is drawn into the syringe, and thirty to sixty minims injected. The after-treatment is regulated by the degree of inflammation. If the hydrocele is large, the needle not attached to the syringe is introduced, to be sure that it is in the cyst. An aspirating needle is now introduced, and the fluid withdrawn. The carbolic acid is then injected through the hypodermatic needle. The operation, in his hands, has given most satisfactory results.

Dr. V. P. Gibney, of New York, then presented a short paper entitled

LESSONS FROM THE MANAGEMENT OF CLUBFOOT,

and for the convenience of the discussion directed attention to (1) the abuse of tenotomy. He claimed that tenotomy is indispensable in the management of certain forms of clubfoot, and that it is abused by failing to make a complete division of the tendon or tendons proposed, by the failure on the part of the operator to correct the deformity after the operation in congenital clubfoot; by too much correction in paralytic cases; by redividing tendons through cicatr cial tissue, and by incomplete after-treatment. He advocated immediate redressment in congenital clubfoot, even to the point of over correcting the deformity.

In paralytic clubfoot, his custom is to delay redressing the deformity until ten days have elapsed, and then to stretch, gradually, the new tissue formed between the severed ends of the tendon. Many failures are due to the lack of long continuance of apparatus, and the failure to keep said apparatus in repair. In his experience the only cases in which calcaneo-varus has followed a tenotomy for equinus were those where the limbs were in spastic contraction.

(2) He made a strong plea for the early treatment of clubfoot, for the reason that cases can be more easily managed; secondary bone and muscular changes will not take place, and the child will have no vicious habits to correct after it begins walking. To carry out early treatment, the assistance and cooperation of the mother or nurse are very important. The first step in treatment, at this early age (from three to six weeks), is to overcome the varus, without any effort whatever to correct the equinus. The correction of the varus is not alone sufficient, but the foot must be brought to an *equino-valgus* before the second stage begins, namely, the correction of the equinus. The division of the tendo Achillis is essential to the relief of the equinus.

(3) He expressed very little faith in "rapid cures," especially in very young children, or in those cases where resort is not had to tarsoclasis or tarsotomy.

(4) By tarsoclasis he meant the forcible breaking down of all obstructions by manual or instrumental force, with or without the employment of division of tendons and fascia, subcutaneously or by the open method. He presented Dr. Bradford's tarsoclast and limited its use to resistant and inveterate cases between six and sixteen years of age. As a dressing after operative procedures, he advocates the plaster-of-Paris bandage, where suitable apparatus is not convenient; this gives the surgeon an opportunity to secure the necessary apparatus at his leisure.

If tendons or fascia are to be divided in the plantar region, he advocates a modification of the open method as practised by Phelps. This open method is applicable to a certain class of cases, and he concluded his paper by calling attention to the importance of a proper classification of cases from a therapeutic standpoint, and deprecated the idea of subjecting every case of clubfoot to a single method of treatment. Success, he claimed, depends more upon the management of a case, and especially the management of the after-treatment, than upon any special method devised.

Dr. Phelps stated that his rule in tenotomy is to put the foot on the stretch, and divide the part that first offers resistance. The neck of the bone is to be divided last. He exhibited drawings illustrating the dressing of clubfoot. When the treatment is begun, elastic force should not be employed.

Afternoon Session.

THE COMMITTEE ON THE PRESIDENT'S ADDRESS

reported that the recommendation with reference to permanent members had been acted upon by the adoption of a resolution offered yesterday. It recommended that the names of such permanent members be announced to the Society, and, if no objections were made, that they be elected by the Society.

The recommendations of the Committee were then taken up seriatim.

Dr. Roosa moved to make the necessary amendment to the By-Laws, with the amendment that, if there be any objection, it shall be referred to the Committee on Ethics. Adopted.

With reference to meeting on alternate years at some other place than Albany, the Committee recommended no change. Adopted.

With reference to the honorary degree of Doctor of Medicine, no recommondation was made and no action was taken.

The Committee emphasized the President's position with reference to the bill for a State Board of Medical Examiners. Adopted.

The Committee recommended that the President-elect be authorized to appoint the Permanent Business Committee as soon as possible. Adopted.

The report of the Committee on Communication from the New Jersey State Medical Society was adopted

Dr. Porter moved that the President nominate a Special Committee to report at the next annual meeting what changes, if any, should be made in the number and terms of delegates from County Societies and other organizations.

Dr. R. F. Weir, of New York, then read a paper on

THE ANTISEPTIC IRRIGATION OF JOINTS FOR CHRONIC SEROUS SYNOVITIS.

He was convinced that this is an excellent method of treatment in chronic serous synovitis. It can be used in hydrops articuli. He recommended it in simple synovitis which resisted treatment longer than a month. The puncture is made at the inner or outer side of the synovial pouch, counter-pressure being made on the opposite side. This should be done with a large canula to permit the escape of flocculi. The joint is then irigated with a 1 : 20 solution of carbolic acid from a fountain syringe. The fluid flows off, and the injection should be repeated until it returns clear. The canula is then withdrawn and the wound treated antiseptically. Moderate reaction occurs, which subsides in a short time. A posterior splint is then applied, which is removed in ten days. Where the joint affection occurs in zymotic diseases corrosive sublimate solutions have been preferred by some. Seven cases were described.

Dr. Gerster said that he had found a five per cent. solution of carbolic acid useful in chronic hydrops for its irritant action. Where the contents are turbid and evidences of inflammation are present, corrosive sublimate solution, he thought, is better than carbolic acid. Where flocculi were present he had found it necessary to make an incision to remove entirely all the contents of the joint.

Dr. William Hailes, of Albany, read a paper entitled

WATER ANALYSES,

in which he described the results of the examination of water from springs, rivers, and wells of the State, with reference to their effects on culture material.

Dr. W. F. Mittendorf, of New York, then read a paper upon

REMOVAL OF A PIECE OF IRON FROM THE INTERIOR OF THE EYEBALL,

by means of a counter-opening. A man who was employed in drilling holes was struck in the eye with a piece of iron from a hammer. The piece of iron passed through the upper lid of the left eye and entered the globe near the inner canthus. The ciliary body and lens were uninjured. The ophthalmoscope showed a partially cloudy vitreous. At the lower part of the vitreous a triangular opening was made through the sclera, which was followed by the escape of a brownish fluid. The point of a permanent magnet was introduced, but without success. The iris forceps were then introduced and a piece of iron removed. Mild iridocyclitis followed, but the patient left the hospital ten days later, being able to count fingers at several feet.

Dr. Roosa thought it important to reaffirm the truth, that the danger of sympathetic inflammation is not passed when the foreign body is removed. It is good practice to remove the body when it can be done without too much injury.

Dr. Noyes, of New York, reported three cases in which he had used powerful electro-magnets, and from his experience he drew the following conclusions:

When a foreign body is to be removed by the magnet, it is not always best to explore the wound. The incision should be in the equator of the eye, and better in the lower hemisphere. The incision should be large enough to permit removal of the foreign body. If the first attempt is unsuccessful, a second attempt some weeks later may be successful, from the effect of the processes of absorption. In rare cases sight is saved. In successful cases the ball is saved and is not as great a source of danger as it was before removal.

Dr. L. D. Bulkley, of New York, read a paper on

UNUSUAL METHODS OF ORIGIN OF SYPHILIS.

His conclusions were: 1. Syphilis is not necessarily a venereal disease, but in a considerable proportion of cases it is acquired innocently, and often in a most unexpected manner. 2. The failure to obtain a venereal history, or evidences of local sores on the genitals, past or present, need not prejudice the diagnosis of a doubtful syphilitic lesion. 3. The syphilitic poison need not be acquired from any known source; the virus is capable of indefinite preservation, and may be communicated in a mediate manner, even through long distance and after some period of time. 4. Non-venereal chancres have frequently been treated and even excised as epitheliomata. 5. Non-venereal syphilis, so far from being mild and to be slighted, often exhibits great malignity.

Dr. Fessenden N. Otis, of New York, read a paper entitled

THE LIMITATION OF THE CONTAGIOUS PERIOD OF SYPHILIS IN RELATION TO MARRIAGE, ETC.

He first referred to the literature of the subject. Syphilis, he said, is never communicated directly from the

father to the fœtus. The mother must be infected. The semen is innocuous. There is no well-authenticated case of communication of syphilis, after the active or secondary stage. When the accumulation of all material causing the lesions of the secondary stage has been eliminated, the disease is no longer contagious. The tertiary symptoms are not necessarily syphilitic, but sequelæ. He considers it absolutely proved that lesions of the tertiary stage are not contagious; that there is possibility of spontaneous cure of the contagious stage; and that the limit of the contagion may be fixed at a period of five years.

Dr. D. H. Goodwillie, of New York, then read a paper on the

TREATMENT OF TERTIARY SYPHILIS OF THE NOSE, MOUTH, AND THROAT.

He held that diet and hygiene are to be carefully regulated. While mercury is valuable in the early stage, it is not useful in the treatment of the sequelæ. Iodide of potassium is beneficial if properly employed, but if pushed too far it may be injurious. For the removal of diseased bones, he uses a revolving burr. He presented a number of drawings and models of cases operated upon, and exhibited an electro-motor and storage battery for operating the burr.

Dr. C. R. Agnew, of New York, presented a paper

ON THE HYGIENE OF THE EAR,

based upon the records of more than 2800 cases. The great frequency of diseases of the middle ear emphasizes the importance of the hygiene of this region. Out of 2844 consecutive cases which came under his observation, 2183 were of diseases of the middle ear.

Evening Session.

The President, Dr. A. Vander Veer, of Albany, delivered

THE ANNIVERSARY ADDRESS.

He chose for his subject *The Water-supply of our Cities and Villages*, and the conclusions he presented were that we should, if possible, procure water, if needed for domestic uses, first by gravity and from mountain streams, lakes, or springs; next, if the former is not possible, then, the surroundings being safe and proper in every respect, by the Gang siphon driven wells. Next by a system of storage, but so arranging the reservoirs that proper aëration can be employed; and lastly, if necessity compels and it must be taken from sources known to be polluted, then a thorough system of filtration should be employed, and the water as completely oxygenated as is possible before distribution.

Thursday, February 4.—Third Day.

Morning Session.

After prayer, by Father Terry, the Committee on Hygiene reported progress.

Dr. D. B. Simmons, of Poughkeepsie, read a paper on

LEPROSY IN JAPAN.

The disease, he said, is confined to no class, and affects both the rich and poor. Those with light complexion, blushing easily, appear most likely to be affected. In the children of those affected a light color of the retina has been noted; and in confirmed cases there is hypertrophy of the right heart. The disease is regarded by the people of Japan as essentially hereditary. He earnestly opposed the idea of infection.

Dr. Bell thought that in Minnesota and Wisconsin, where Norwegian colonists have settled, there should be sanitary regulations enacted to prevent the intermarriage of persons in whom this disease is hereditary, and thus to prevent its appearance in this country.

Dr. William H. Bailey, of Albany, read a paper on

THE TREATMENT OF HEMORRHOIDS IN PREGNANCY,

He referred to the frequency of the condition and the absence of reference to it in the text-books. In reference to its treatment before confinement, he advised regulation of the bowels with a pill of aloes, hyoscyamus, and ipecac; after confinement, with a mixture of sulphate of magnesia, carbonate of magnesia, and sulphur. In cases in which the hemorrhoids are pressed out, he uses warm fomentations.

Dr. Ely recommended in those cases in which the hemorrhoids tend to protrude, the use of a rubber bandage passing between the thighs and secured to a muslin bandage passed around the waist. This may also be used in males.

Dr. W. H. Thomson, of New York, then read a paper on

THE PREVENTION OF HEMIPLEGIA.

He said that the impending danger may be recognized long before it occurs. The subject of prevention was taken up under the head of the three forms of embolic, syphilitic, and vascular hemiplegia. The embolic form cannot be prevented, except in so far as attention to the condition of the heart is concerned. The syphilitic form is preceded by and accompanied with headache and partial and varying paresis. Hypodermatic injections of corrosive sublimate were recommended for the removal of the perivascular inflammation. If the temporal artery be prominent, it indicates obstruction. The artery may become prominent by overdistention or from changes in its wall. If there is obstruction, the pulse becomes hard and long in its vibration, and this gives a deceptive feeling of strength, the pulse being incompressible. In the urine, unfavorable conditions are absence of color and low specific gravity. If the paleness of the urine is due to a nervous cause, it has no significance. In albuminuria with good color and average specific gravity, there is not much danger of hemiplegia.

An important element in the causation of hemiplegia, is the sudden increase of blood-pressure. The indications for treatment are, first, the employment of measures to lessen arterial tension; second, prevention of the accumulation of blood poisons by means of free respiration in the open air; and, third, removal to a mild climate. Chilling of the surface is to be avoided by use of suitable clothing. Much food should not be taken at any one time. From midnight to sunrise is the most dangerous period of the twenty-four hours. Excess of nitrogenous food is to be avoided. Fermented milk, prepared by the Arabian method, was recommended, also fish and vegetables. Abstinence from alcohol was most strongly advised and it was stated that tobacco should be avoided. Of medicines, small and repeated doses of corrosive sublimate, one-thirtieth of a grain,

were recommended. Benzoate of sodium was stated to be useful in lowering arterial tension.

DR. F. C. CURTIS, of Albany, then read a paper on

RINGWORM OF THE SCALP,

with special reference to its treatment. In private practice, this disease is generally very amenable to treatment; under the use of depilation (which is feasible where the involved area is small), daily scrubbing, and a mild parasiticide. But in asylums and children's hospitals, the large number of cases usually affected makes individual treatment less easy, and the atmosphere and the surroundings of so many affected with it make it much more intractable. In a recent outbreak in a children's hospital, several remedies were sought which would be effective without the tedious work of depilation. Oleate of copper was first used, but it was found of no value. Then several methods of using chrysophanic acid were tried; in a ten per cent. solution with liquor guttæ perchæ, as proposed by Dr. Alexander, painted on after shaving, and freshly applied every week, it was found but slightly irritating and moderately effective, a few being cured and in most the intensity of the disease being lessened; a one and one-half drachm to the ounce ointment, applied after shaving and the spots then strapped with adhesive plaster, was effective in cases in which the areas affected were not too extensive. A seven grain to the ounce solution in chloroform was used with depilation after other remedies had been employed, and by it a number of cases were cured. In a proportion of the cases it was found possible to eradicate the disease without depilation by chrysophanic acid and the air-tight application first mentioned. In those cases in which the disease remained intractable, the chloroform solution and an ointment of carbolic acid and red oxide of mercury, with depilation, effected the final destruction of the fungus. The epidemic was relieved in about four months after treatment began.

DR. F. R. STURGIS, of New York, spoke of the value of shaving beyond the margin of the diseased area, followed by blistering and the subsequent application of parasiticides. This is limited to cases in which the area affected is small.

DR. CHARLES CARY, of Buffalo, read a paper on

CREMATION.

He said there is an absolute demand for cremation, especially in populous places. He gave the history of cremation, and the process of incineration, as practised in Buffalo, was described.

The Committee on Nominations then presented their report, and the following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—W. S. Ely, M.D., of Rochester.

Vice-President.—Solomon Van Etten, M.D., of Port Jervis.

Secretary.—Wm. Manlius Smith, M.D., of Syracuse.

Treasurer.—Charles H. Porter, M.D., of Albany.

Censors. Southern District.—J. S. Warren, M.D., of New York; Walter B. Chase, M.D., of Brooklyn; and E. T. Brush, M.D., of Westchester Co. *Eastern District.*—Joseph Lewi, M.D., of Albany; M. J. Burton, M.D., of Troy; and Leroy McLean, M.D., of Troy. *Middle District.*—L. Griffin, M.D., of Binghamton; Robert Frazier, M.D., of Oneida Co.; and J. M. Gofi, M.D., of Cazenovia. *Western District.*—Theodore Dimon, M.D., of Auburn; M. S. Kittinger, M.D., of Lockport; and David Little, M.D., of Rochester.

For College of Medicine, Syracuse University.—H. Nims, M.D. of Onondaga Co.

Committee on Medical Ethics.—A. Jacobi, M.D., of New York; Arthur Mathewson, M.D., of Brooklyn; and J. Whitbeck, M.D., of Rochester.

Honorary Members.—Mr. Lawson Tait, of Birmingham, Eng.; Jos. G. Richardson, M.D., of Philadelphia; and Dr. Hansen Grut, of Copenhagen.

DR. FLOYD S. CREGO, of Buffalo, then read a paper on

MIGRAINE.

He pointed out the tendency of this affection to be hereditary. A study of its clinical history shows that it is rarely acquired after the age of twenty-five and that it declines in frequency after the age of fifty. It is equally common to both sexes. It bears a close relation to nervous affections and the bilious, gastric, and vasomotor theories of its origin are incorrect. The true theory, he believed to be that of nerve storm, allied to epilepsy. In its treatment he advocated the use, between the paroxysms, of minute doses of the bromides continued for months.

DR. F. W. HINKEL, of Buffalo, then reported a case of *Tubercular Ulceration of the Pharynx*, which ended fatally in a month.

DR. FRANCIS M. HAMLIN, of Auburn, read a paper on

THE EMISSION OF SEMEN AS A MEANS OF DIAGNOSIS OF DEATH BY HANGING.

He held that this is more constantly present than is generally supposed; and that when there is no external appearance of semen, pressure upon the urethra will cause its appearance. He thought it possible that this may occur in cases of sudden death from other causes; but to establish this point further observations are required. He recommended the following method for discovering seminal stains on cotton cloth: Put two drops of water on a glass slide, and then lay on the water a small piece of the muslin containing the supposed stain; fray out the ends and let it remain for five minutes; then examine the slide under the microscope. If the stain be on woollen cloth, shave off a portion of the stain, and treat the specimen thus obtained in the same way.

After a vote of thanks to the President and other officers, and to the committees, the Society adjourned, to meet in Albany, on the first Tuesday in February, in 1887.

THE PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, November 28, 1885.

THE PRESIDENT, S. WEIR MITCHELL, M.D., IN THE CHAIR.

DRS. CHARLES K. MILLS and JAMES HENDRIE LLOYD read

NOTES ON THE DIAGNOSIS OF SPINAL TUMOR.

The subjects of general and differential diagnosis of spinal tumors were alone considered; that of local diagnosis—*i. e.*, of position of the growth at different levels of the spinal axis—was deferred for another paper. The

conclusions were based on a study of fifty cases, three of which were personal observations, and the remainder were collected from American, English, French, and German literature. The general diagnosis can be made from a certain train of symptoms. These are of two classes: (1) Those which are directly indicative of such a lesion; (2) Those which are corroborative. The facts which point directly to a growth within the canal are: History of a constitutional or other cause, as of syphilis, cancer, tuberculosis, or traumatism. The onset and development are gradual and of a peculiar character. The first symptoms are those of an irritative lesion. This is probably due to the fact that tumors usually involve the membranes, as demonstrated by the cases studied. Pain in the back or limbs is usually, but not always, present. The *sensory phenomena*, such as hyperæsthesia, anæsthesia, and paræsthesia, come on with more or less rapidity, with oscillating and irregular manifestations. *Motor symptoms*, such as paresis, spasm (tonic or clonic), contracture, tremor, ataxia, also manifest themselves in a similar vacillating manner. Exaggerated *reflexes* present themselves in most cases. *Trophic* and *vaso-motor disturbances* develop as the lesion progresses. These are such as wasting, ischæmia, œdema, and decubitus. *Visceral disorders*, such as paralysis of the bladder or rectum, or of their sphincters, and disorders of the heart and respiration, are, sooner or later, marked symptoms. Vomiting, gastric and intestinal disorders are present in a limited number of cases. Mental disorders are present in only a very limited number of cases of tumors high in the spinal axis, and are not of diagnostic importance. Briefly stated, the phenomena which point with comparative certainty to the existence of spinal tumors are symptoms of meningeal irritation gradually increasing, and symptoms of slow compression of the cord.

The data in the cases studied were somewhat meagre as to duration. The usual duration is from six months to three years.

It may be noted that fever was present at some stage in a considerable percentage of cases, but was so irregular as not to be of much diagnostic value.

The differential diagnosis of spinal tumors was considered in reference to the following affections: Spinal congestion, hemorrhage, meningitis, caries, traumatisms, sclerosis, aneurisms, neuritis, metallic and infectious disorders, and hysteria.

Spinal tumors are of constitutional or special origin, as syphilis, cancer, tuberculosis, etc.

Onset is gradual and irregular. Duration is comparatively long.

Progress is gradual, by irregular advances, toward a fatal termination.

Symptoms are inclined to be irregular, *i. e.*, unilateral or local; later, bilateral. Special symptoms, as paralysis, spasm, sensory and visceral disorders, irregular as to time.

Decubitus and trophic changes are common late.

Reactions of degeneration are often present.

In *spinal congestion*, constitutional cause not present.

Onset is usually sudden and after exposure. Duration is short, from a few days to four months.

Disease is stationary, then retrogression of symptoms toward recovery occurs.

Symptoms are more uniformly bilateral; motor and other symptoms develop about same time.

Decubitus is rare.

Reactions of degeneration are not usually present.

In *spinal hemorrhage*, there is no special history, or history of cardiac or vascular degeneration.

Onset is sudden.

Progress is more regular.

The first symptoms persist, and secondary degenerations follow, and differ according to extent and location of lesion, but are more likely to be uniformly bilateral.

In *meningitis*, the symptoms of localized compression are absent. The girdle symptom is absent. The affection is sometimes curable.

Reactions of degeneration are absent.

In *caries*, deformity is rarely absent. Rigidity of the muscles of back is a very important symptom.

In *traumatisms*, there is usually a history. The symptoms are those of caries, myelitis, meningitis, or combinations of these, according to the character of case.

In *sclerosis*, the symptoms are usually of progressive systemic affections. Compression symptoms are absent.

Duration is longer.

Progress is gradual, and more regular.

Aneurisms are only to be distinguished when extra-spinal, causing erosion and compression.

In *neuritis*, there are irregular sensory, motor, and reflex disturbances; compression symptoms and visceral disorders are absent. It is curable.

In *metallic and infectious disorders*, a history of definite causation is present. In metallic disorders there may be special characteristic signs, such as lead line, etc.

In *hysteria*, a precedent hysterical history is usual.

Onset is often sudden. An emotional element is present. The symptoms are bilateral. Trophic changes are absent. No reactions of degeneration are present.

DR. E. N. BRUSH presented

THE BRAIN AND SPINAL CORD REMOVED THAT DAY FROM A CASE OF GENERAL PARESIS.

The case was an interesting one in connection with the question of the association of the physical and mental symptoms of paresis. In this instance physical symptoms preceded the mental by some months. In the winter of 1883–84 the patient was discovered by his physician to be ataxic; symptoms of posterior spinal sclerosis increased, and in January were associated with some mental disturbance. The patient was irritable and forgetful, but in a general way complacent. He thought his business was unusually successful, and that he possessed remarkable ability to transact business affairs. He was easily confused, and in attempting to make a short journey alone over a route with which he was perfectly familiar lost his way, and found himself several miles from his home on the wrong train.

His mental disturbance became more aggravated, and at last it became necessary to place him in a hospital. He was first placed in a private institution in a neighboring State, but there—doubtless after a slight epileptiform seizure—became so much disturbed that his removal was requested. In August last he was admitted to the Insane Department of the Pennsylvania Hospital.

On admission his mind was markedly impaired. He was complacent, quietly submitted to suggestion, and was apparently demented. There were considerable disturbance of speech, marked tremor of tongue and

lips and of upper extremities. Patellar tendon reflex abolished; pupils contracted to pinpoints and not responsive to light; Argyll-Robertson symptom was present; gait ataxic.

During his time in the Hospital the patient had three epileptiform seizures, such as are met with in cases of paresis. From these he readily recovered, but with increased impairment of mental and physical powers. After two of the seizures he was aphasic for some hours.

At eight o'clock on the morning of the day of his death, the patient had a slight vertiginous attack, followed by loss of power in arms and legs to a great degree, and disturbance of the power of coördination to such an extent that he could not, except after repeated trial, direct his hand to grasp an article held up before him. He protruded his tongue, opened and closed his eyes, and did other simple things upon direction; but to everything responded "yes," and did not seem able to articulate anything else.

At 3.30 P. M. the nurse's attention was attracted by the dusky appearance of his face, which had previously been pale.

The patient was seen at once by Dr. Brush, who found his face almost cyanotic, eyes injected, pupils closely contracted. In a few minutes he had a severe convulsion. At this time his temperature was 102⅖° F. The convulsion continued, and at 4.15 the temperature was 108½° F. Death occurred at 5.45. The temperature was then 107⅗°, and the body was bathed in perspiration. An hour after death the temperature of the body was 107° F. Post-mortem rigidity came on rapidly, and at eight o'clock was very pronounced.

Examination, sixteen hours after death: The conditions found were but briefly referred to, as the speaker intends to report this and some other cases more in detail to the Society.

The skull, especially in the temporal region, was quite thin; the dura was strongly adherent to the skull, and along the median fissure to the arachnoid pia; the arachnoid was thickened and opaque over the frontal and temporal convolutions, and along the Sylvian fissures; the pia in these locations was intimately connected with the cortex, and could not be separated without tearing it or the cortex cerebri. The sections made through the brain showed marked sclerosis; indeed, sections made through the anterior convolutions gave considerable resistance to the knife. The cord in the middle dorsal region was much injected.

NEWS ITEMS.

WILLIAM LAMBERT RICHARDSON, M.D., has been appointed to the Chair of Obstetrics in the Harvard Medical School.

THE OFFICERS OF THE CONGRESS.—*The Berliner klinische Wochenschrift*, in its issue of January 14, 1886, publishes the new list of officers for the Congress, and adds: "We miss many names of high repute in Germany."

THE NEW CONGRESSIONAL DIRECTORY gives the names of the physicians who are members of the present House of Representatives. The list comprises Drs. W. H. Cole and F. T. Shaw, of Maryland; Drs. I. M. Evans and L. E. Atkinson, of Pennsylvania; Dr. W. H. Ellsberry, of Ohio; Dr. John Swinburne, of New York; Dr. R. T. Davis, of Massachusetts; Dr. A. M. Dockery, of Missouri; and Dr. J. H. Gallinger, of New Hampshire.—*Maryland Medical Journal*, Jan. 30, 1886.

PHILADELPHIA CLINICAL SOCIETY.—At the annual meeting of this Society, held January 22, 1886, the following officers were elected for the ensuing year:

President.—Dr. John B. Roberts.

Vice-Presidents.—Dr. Clara Marshall, and Dr. Daniel Longaker.

Recording Secretary.—Dr. J. G. Heilman.

Treasurer.—Dr. L. Brewer Hall.

COCAINE A DANGEROUS DRUG.—A bill is being prepared by the New York County Medical Society asking the State Legislature to include cocaine in the list of drugs forbidden to be sold excepting on physicians' prescriptions. It is said that in New York many drug stores sell a paste made of coca leaves and lime, forming a cud similar to that used by the Peruvians as a stimulant. These preparations are in great demand.—*Southern Medical Record*, January 20, 1886.

HYDROPHOBIA.—The Secretary of the Antivivisection League of England argues, in a letter to M. Pasteur, that cauterization removes all danger of hydrophobia. Her son once, and she herself five or six times, have thus escaped the malady, and both offer to be bitten by any mad animal in M. Pasteur's laboratory, on the condition of being allowed to treat the wounds themselves.—*Amer. Pract. and News*, Jan. 23, 1886.

OBITUARY RECORD.—Died at Danville, Pa., on January 19th, after a brief illness, ALONZO AMERMAN, M.D., in the thirty-sixth year of his age.

NOTES AND QUERIES.

ERRATUM.

IN our issue of January 30, page 139, 12th line from bottom of second column, for "lessened *invariability*" read "lessened *variability*."

HYDROCHLORATE OF COCAINE IN STRICTURE.

NOT having seen any published account of the successful use of this valuable drug in stricture, I am able to report its efficiency in some cases at least. In a recent case where it was necessary to catheterize daily, and where a small instrument could not be passed on account of a painful stricture not far from the meatus, a few drops of a four per cent. solution of cocaine, applied by means of a common glass dropper, rendered the passing of the catheter *easy* and *painless* without systemic effect.

Respectfully, F. G. BYLES.

FREDONIA, PA., January 29, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 26 TO FEBRUARY 1, 1886.

SUMMERS, JOHN E., *Colonel and Surgeon.*—Retired from active service, by operation of law, January 24, 1886.—*S. O. 20, A. G. O.*, January 25, 1886.

WATERS, WM. E., *Major and Surgeon.*—Granted leave of absence for one month and fifteen days.—*S. O. 5, Division of the Atlantic*, January 23, 1886.

VICKERY, RICHARD S., *Major and Surgeon.*—Assigned to duty in connection with the Army and Navy Hospital, Hot Springs, Ark.—*S. O. 24, A. G. O.*, January 29, 1886.

BANISTER, J. M., *Assistant Surgeon.*—Ordered for temporary duty at Fort Warren, Mass.—*S. O. 16, Department of the East*, January 23, 1886.

PHYSIOLOGICAL STUDIES OF THE KNEE-JERK, AND OF THE REACTIONS OF MUSCLES UNDER MECHANICAL AND OTHER EXCITANTS.

BY S. WEIR MITCHELL, M.D.,
MEMBER OF THE NATIONAL ACADEMY OF SCIENCES,
AND
MORRIS J. LEWIS, M.D.,
ASSISTANT PHYSICIAN TO THE INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA.

THE phenomenon known as tendon reflex, knee-jerk, myotatic contraction, has won steady attention since Westphal pointed out its value. Indeed, as regards what we may call its natural history there seemed little of a novel nature to be learned. The discussion as to its true parentage has also been narrowed so far as to enable us to feel sure that the blow on a tendon causes motion in the related muscle, not owing to an afferent impression from the tendon, but either to a direct irritation of the muscle concerned—*i. e.*, direct muscle response, or to the pull on the muscle causing afferent sensory impressions to the cord, and efferent motor response—*i. e.*, reflex action.

At this point we leave the matter for a time to turn to our own researches on the normal history of the "knee-jerk."

We shall relate in detail all the results we have so far obtained, and shall then endeavor to show the relation some of them bear to the possible theoretic explanations of the cause of the knee-jerk.

Our point of departure was a remark of Dr. Buzzard's, in a debate before the London Medical Society, in regard to Jendrássik's discovery, now three years old, as to the power of violent volitional muscular acts to increase the amount of the knee-jerk.

Jendrássik, in his essay,[1] states in a too brief paragraph that if, when the patellar tendon is struck, the patient clinches his hands, or makes other violent movement, the coincident jerk is increased. His other conclusions are: that the knee-jerk is a true reflex caused by mechanical irritation of the nerves in the tendon; that the muscle must be in a condition of passive tension; that voluntary innervation of the crural nerve lessens the reflex, or prevents it altogether; and that innervation of the sciatic favors the knee-jerk.

As the word knee-jerk will, of necessity, be frequently repeated in this article, it will be hereafter spoken of as k.-j.

[1] Beiträge zur Lehre von den Sehnenreflexen, von Dr. Ernst Jendrássik. Deutsches Archiv für klinische Medicin, vol. xxxiii. page 175, 1883.

Our own research has led us to examine with care—

1. The circumstances which increase, and those which lessen the k.-j., and to consider the influences exerted by volition, motion, sensation, electricity, tension, etc.

2. The characteristics of direct muscular motion caused by a blow, and the effects on it of voluntary motion, sensation, electricity, tension, etc.

These portions of our work must be regarded as contributions to a branch of normal physiology. We have kept them apart from the brief speculations which follow as to the theory of tendon reactions, and of the various novel phenomena which we shall describe.

Manner of obtaining the knee-jerk, and its normal variations. The experiments which give the best result are made by placing the subjects, healthy young men, on their backs on a lounge, so that they rest absolutely without muscular exertion. It is necessary or best that their hands be at rest, their eyes passive, and that they neither laugh, cough, speak, nor swallow, except when it is desired to test the effects of these acts on the phenomenon to be studied.

If the subject be seated, many of the results—indeed, all the coarser ones—can be had, but the more delicate experiments are apt to fail. The legs are allowed to hang over the foot of the lounge at varied angles with the thigh, which is itself bent at a very obtuse angle with the trunk. It is better for some of the experiments, however, to let the lower end of the thigh rest easily on two rubber pads placed at the sides of a wooden support, which is cut out below, so as to prevent pressure on the back of the thigh, and this for reasons which will appear elsewhere. Thus placed, the thigh is free from pressure, except where the tuberosities of the femur rest upon the pads, and the leg is at liberty to swing.

At the risk of being tedious, it is well to explain the modes of exciting the k.-j. so as best to get the effects of coincident and remote impressions. With a rubber percussion hammer, which should have a slightly elastic steel handle, and be not too light nor too hard, blows are struck on the tendon at intervals, or else a more or less constant excitement of the muscle is kept up by a series of quickly repeated taps. A sort of partial tetany is thus caused, and with care can be made quite equal, so that any new element of increase is easily seen. This, perhaps, is the best method for the more delicate tests. A good plan is to place across the tendon an oblong piece of rubber, and to strike on it. Still better is it, in sensitive persons, to place one's forefinger across the tendon, and to strike on this. We get thus a double means of judging the force used, because we can feel the responsive succession of jerks

of the tendon on the sensitive palmar face of the finger. A good impression is thus obtained of the briefness of the interval between the time of the blow on top of the finger and the time of the answering jerk of the tendon beneath it. Other and obvious precautions are needful at times, such as absence of constricting clothes, care to prevent swing of the pendant leg when struck.

The k.-j. varies in quality in healthy men. In some the same weight of blow causes pretty constant effects when steadily repeated at like intervals, but in others the effects are inconstant, and a series of slight motions are apt to be followed by an excessively exaggerated act. Such persons make bad subjects for experimentation.

This explosiveness is also apt to follow much excitation of the muscle.

Even in the young and healthy the k.-j. varies remarkably. On the whole, it is less good in the evening than early in the day, and possibly relaxing states of weather, as we shall show further on, may be capable of lessening these muscular responses. When familiar with the normal of one person's k.-j., it becomes easy to see that at times when he is not well or is exhausted, and especially, as we have said, toward ten at night, there may be some distinct lessening of the ease of muscular reply to the tap.

In one case of a healthy man, over fifty, there is often a good k.-j. in the morning in the left leg, and none, or almost none, later in the day; whilst, in the other leg, the jerk varies naturally from day to day, and is sometimes singularly good in both legs. A meal and three or four glasses of wine seem in him to favor its increase. Daily repeated excitations through the knee-tap in some healthy persons enormously increase the ease and amount of muscular response. In one case we even felt some concern at the exaggeration of the symptom we finally produced. In some people the muscle soon ceases to contract if the taps be often repeated, at one sitting; in others as healthy, it is very difficult to wear out the power of reply.

Effect of voluntary acts on knee-jerk. While the subject was at rest, as described, the tendon was struck at intervals by an assistant. An effort was made to move the scalp voluntarily, so as to make the volition coincide in time with the tendon tap. When successful, the k.-j. was increased.

The movement of one ear, an act only possible with a few subjects, reinforces the k.-j. Frowning increases k.-j. Distinct but not violent winking increases k.-j., when coincident with the tap and in good subjects. Thus if we wink and strike at different intervals an accidental synchronism reinforces k.-j. Winking forcibly with either eye gives like results, and one eye can thus reinforce k.-j. for either leg. Rolling the eyes from passive central fixation to extreme limit of motion adds to k.-j.; a sudden convergence on a very near point does the same; but these beautiful experiments failed when the subjects were seated, and succeeded when they were supine and used the knee crutch described.

Inspiratory and expiratory acts, if volitional and decided, increase k.-j., especially at the beginning of the movements; and if we suddenly fix the chest either in a full or partly empty state, there is a like result but not well marked.

A laugh or sneeze remarkably increases k.-j. Phonation gives in many people admirable results. To obtain these let the passive supine subject sound, with emphasis, the letters in turn, but so slowly that time may be allowed for a tap on the tendon to be made between each letter as well as with each act of phonation. When this is done, the exaggeration of the k.-j. can be well seen when the knee-tap coincides with the utterance, as contrasted with the lesser effect of the tap between each utterance.

Deglutition gives also very positive increments to the k.-j., but less surely than strong phonetic acts. To avoid chance of some volitional reinforcement, most of these experiments were repeated on ignorant persons to whom an assistant gave a signal to perform a certain act, or who were told to wink or to sound vowels, whilst the operator noted the results. These results are all easy enough to get if we take the precautions mentioned and select men with responsive muscles.

The following coarser muscular acts increase k.-j.:

Action of platysma myoides.

Turning the head strongly.

Drawing in the belly.

Rotation of body on pelvis.

All these acts increase the k.-j. most during the movement and least when the act is complete.

Arms and hands. These parts give, when in forcible action, great increase of k.-j. Elevation of the arms and all other strongly done acts, but especially violent clenching of the hands, are effective. The moment of greatest effort slightly precedes the maximum of reinforcement to the k.-j. Slow or gentle movements give little or no effect.

In a strong, right-handed man, violent closure of the left and much weaker hand gave less addition to k.-j. than similar effort with the right hand. Either hand, with equal amount of action, seemed to affect alike the knee of its own or the opposite side. Motion of one finger suffices to reinforce k.-j.

Legs. Strong movements of the toes in flexion or extension in the leg struck or in the other much increases k.-j., and apparently either act gives an equal result, for its own or the other leg. Large motion of one leg in flexion and extension increases k.-j. of its fellow. The muscular acts of the leg struck were carefully studied, and the more so because our results do not precisely agree with some of the conclusions of Jendrássik.

Voluntary use of quadriceps extensor. All strong contractions of the muscles concerned in k.-j. abolish it entirely. With some care we may eliminate the synchronous activity of the opponent flexors of the leg and so get an expression of the pure voluntary action of the extensor. Thus with the leg of a sensitive subject at a good angle for k.-j. have the foot held, or stay it against some immovable obstacle. Then let him will to extend the restrained foot and with a little trial it will be found that the extensors can be called into isolated activity. If they be strongly contracted, no matter at what angle be the leg, all k.-j. ceases. Now relax them a little and then most suddenly the k.-j. returns in excessive de-

gree. It is curious to note it coming and going with increase or decrease of contraction of the muscles concerned.

Therefore, all violent innervation of the crural nerve prohibits k.-j. All milder innervation increases it. When a movement of the quadriceps extensor is willed about equal to that produced by a tap on the tendon, and a tap is made to coincide with it, an interesting result is obtained. If the act be timed correctly the result is a large sudden movement, which has to the observer, who is thus struck, little of the qualities of an act of will. It is abrupt, jerky, and does not seem to be moderated or passively antagonized as are our ordinary voluntary motions. It has only the peculiarities of a knee-jerk.

Action of leg flexors (opponents of the extensor group). With the patient seated, thigh on crutch, the leg is voluntarily flexed from a level with thigh whilst the k.-j. is being tested; good reactions are obtained, but in this experiment both the flexors and the moderating extensors are functionally active. To get the single influence of the flexors, with the thigh on the crutch, and the subject seated, an assistant suspends the passive leg at the ankle whilst the subject flexes the leg gently, the assistant yielding to the motion. There is then no notable extensor activity. Result, good k.-j. Next active flexion is strongly resisted. Result, great exaggeration of k.-j. up to such flexion as abolishes k.-j. by tension, as will be seen further on.

In these latter observations, if well managed, the action of the extensors is excluded. Sciatic innervation, therefore, whether gentle or strong, reinforces k.-j.

As regards all of the foregoing experiments, the reinforcement of the k.-j. lasted while muscular acts were being performed, was best when they were most intense, and continued for an appreciable time after volition had ceased. This continuation of influence was particularly noticeable with the more violent muscular acts.

Effect of continuous efforts. With the subject supine, blows were struck at intervals, and meanwhile the upper extremities, neck, and back were kept in a state of violent muscular fixation. The k.-j., at first excessive, soon became less and less, but did not quite wear out during any length of possible effort, although it continued to be feeble for some minutes after exertion ceased. In the other leg it remained as usual.

Effect of states of tension. These experiments were made with great care, because they have some bearing on the belief expressed by Jendrássik, Tschirjew, and Gowers, that a state of passive tension due to flexion of the leg on the thigh or to other means —*i. e.*, pushing or striking downward the patella— is a needful factor in enabling the tap to cause k.-j. In other words, they help to determine whether or not anything beyond such muscular tension be requisite, as exists in a relaxed muscle.

A blow on the tendon below or just above the knee whilst the limb is passively flexed, of course most readily evolves the k.-j. We have then present two elements, muscular tension from moderate stretching and also circumstances which mechanically favor the k.-j., as the tightened tendon enables us when we strike it to influence more and more abruptly the mass of the muscle. Is the passive tension essential?

In some sensitive but healthy subjects the following experiment succeeds at times:

The subject is seated on the floor, passive, with the back supported. The leg is in full extension on the thigh, and the body at a right angle with the latter. Complete relaxation is thus attained. Then the stiff rubber cushion is placed above the knee, and a blow is struck so as to fall on it at right angles with the line of the muscle, or the pad is so placed as that the force is rather directed a little upward. The position of the tendon above the knee is such that it has under it a cushion of areolar tissue. The blow evolves a distinct jerk of the muscle. The infrapatellar tendon under like circumstances does not give a response, because the blow must take up its slack and that of the suprapatellar tendon before the pull reaches the muscle, but in this position of the leg there is not space enough beneath the slack tendon below the knee to allow this to occur. In the experiment stated, there is no preparatory tension from knee flexion, and we have only ordinary muscular tone as a preparation. That the result is comparable to that obtained when we tap below the knee with a mechanically tense tendon, is shown by the fact that the motion caused by a blow above the knee, managed so as not to push the patella downward, is reinforced by motion elsewhere. They who hold with Gowers that preliminary passive tension is needed to enable a pull on the muscle to excite it, will plead that every blow on the tendon above the knee placed as described acts at one and the same moment to pull on the muscle and to excite it, and this may be true, nor do we see how entirely to eliminate this element of doubt.

If with the leg relaxed, a blow on the suprapatellar tendon, either at a right angle with the thigh or even in a slightly downward direction, so as to depress the patella, causes a muscle response, the time should be that of a reflex and not the shorter time of a direct muscle act, because these methods do at one and the same moment involve and cause muscle tension (reflex preparation, Jendrássik, Tschirjew, and Gowers), and also muscle excitation. This has not been shown as yet to be the case, and until it has been, there seems no reason to seek beyond the existence of common muscular tone to explain the k.-j. If the time should be found to be that of a reflex act, it would favor the idea that the k.-j. should be so considered.

Effect of extreme tension. It is possible to abolish the knee-jerk even in spastic paralysis by increasing the tension of the muscle. I. P., æt. thirty, case of spastic paralysis. The reactions are excessive. He was placed on his face so that the body and pelvis lay on an upward slope. This brought tension on the upper part of the quadriceps extensor. Then the leg was bent slowly, and at a certain angle the k.-j. rather abruptly failed, as it always does under like circumstances in the normal subject.

As *strong* flexion of the leg upon the thigh has

the effect of greatly diminishing or even abolishing the k.-j., the question arose whether this was caused, in part at least, by the great mechanical disadvantage at which the patellar tendon then was placed, as a blow upon it in this position would have the minimum effect upon the muscle. To investigate this point, the subject was placed upon the floor on his side with the underneath hip and knee each at a right angle; in this position a marked k.-j. was obtainable; now, by slowly extending the trunk upon the thigh, keeping the thigh and leg perfectly quiet, an increased tension was made at the *upper end* of the muscle, while the mechanical arrangement at the knee remained unchanged, except as concerned the increased tension: this procedure had the effect of gradually diminishing and at last even abolishing the k.-j. When the subject was placed upon his side, with the body at a right angle to the thigh, and the leg almost perfectly straight, a very slight k.-j. was obtainable; now if the trunk, as before, was slowly extended upon the thigh, the k.-j. increased markedly with the increasing tension, as now the slack in muscle and tendon was taken up by the pull from above, so that the tap on the tendon could make itself felt upon the muscle more markedly; a further flexion of the leg on the thigh now increased the tension too much and diminished the k.-j.

It might be considered by some that extreme tension by pulling on the fibrous sheath of the muscle makes the sheath so tense that any external blow is mechanically hindered from impressing the muscle beneath; but the following very interesting and novel experiment appears to make it possible that there is also present a physiological element, although the mechanical arrangement may have some influence. The poles of the secondary coil are placed, for instance, on the belly of the flexor sublimis digitorum with a current that is sufficient to flex powerfully and very painfully the ring and middle fingers into the palm, so as to put them entirely beyond the control of the will. Then an assistant forcibly extends the flexed fingers and wrist; this procedure at first increases the pain, but by the time the wrist and fingers are fairly extended the contraction and the pain begin to diminish until at full extension pain is almost entirely gone, only a sense of discomfort remaining, and the fingers are again under full control of the will. If now we release the wrist, the fingers return to their powerfully flexed condition and the pain becomes as great as before.

It seems probable, on the whole, that moderate tension is mechanically of use in enabling us to get the fullest k.-j., but is certainly not essential to the evolution of lesser manifestations of the phenomenon. Extreme tension, of course, may make it mechanically difficult to get k.-j., and also to observe it, but it seems likely that there is also involved in this apparent inhibition some physiological obstacle due to stretching of the muscle. The problem is one of great obscurity, and needs laboratory study.

Effect of acts of volition on organs functionally inert or on lost parts. When one of us willed to move his ear, over which he had no control, a considerable increase of k.-j. followed. Persons who have lost limbs often retain the power to will a motion of the absent member, and have then in their consciousness a sensory representation of such motion. It is very remarkable that these patients can never seem to themselves to make sudden, quick, or very complete movements of absent parts. It was needful to be sure that the stump was not moved. With proper precautions, the effort to move by will a non-existent part reinforced k.-j. distinctly in a case of loss of left arm at shoulder, and in a knee amputation. These results have value as proving that the reinforcement is not due to the muscular movement which, in the unmutilated, follows an act of will.

Elbow-, ankle-, and jaw-jerks. These obey as to increase from remote voluntary muscular acts the same law as do the motions due to knee-tap. The elbow-jerk is hard to obtain, but in one or two of our subjects was very good and was reinforced easily by willed toe movements, as also by those of the other hand.

The same remarks apply to the jaw-jerk[1] (chin-reflex), although this movement is not so readily shown in some subjects. This jerk is most easily obtained by allowing the jaw to hang passively, or by gently supporting it with one hand while with the other a blow is struck on the teeth or chin in a downward direction with the rubber hammer.

Effect of one tendon tap on another. Numberless experiments were made to learn if the one k.-j. reinforces the other. Thus we keep the right quadriceps extensor moderately excited by a series of quickly repeated blows on the tendon, and call out the most extreme k.-j. possible in the left leg. We do not add to k.-j. of its temperately excited fellow member.

The normal knee-jerk, ankle-jerk, and arm-jerk do not react on one another. All of these experiments as between the arm- and leg-jerks are difficult to manage, but easy enough as concerns the various leg motions.

The experiment of Jendrássik naturally led us to carry out, in regard to volitional movements, the investigations we have detailed; but we were quite unprepared for some of the phenomena which presented themselves, when we tested the effect of sensory stimulation on the k.-j.

Influence of sensations upon the knee jerk and other phenomena of like nature.

Touch. Mere touch or rough but painless contacts, which call out the well-known subcutaneous reflexes, do not influence k.-j.

Pain. This is a fertile means of reinforcement, as the following experiments show:

The subject being at rest, supine, with the right leg on the crutch, a series of equal blows, at regular intervals, is struck on the tendon. A second assistant takes hold of a hair on the thigh and twitches it so as to cause pain at the moment of one of the blows on the tendon. Nearly always this gives rise to a notable increase of the k.-j. If rapid blows,

[1] "The Chin-reflex: A New Clinical Observation," by Morris J. Lewis, M.D. Philadelphia Medical and Surgical Reporter, May 9, 1885, p 591. Read before the Philadelphia Neurological Society, March 23, 1885.

which keep the foot slightly extended, be used, the pull on the hair exaggerates the k.-j.

A needle-prick on the thigh or anywhere else on the surface of the body or limbs, below the neck, has a like influence, and is better seen when the hands are pained than the arms or trunk. Like hurts to the neck and face, and even more decisive hurts, such as a pull on the moustache, give little result. Needle-pricks are most efficient on the thigh of either side; but all of these phenomena vary with the individual; the efficiency of all such influences wears out after much repetition.

Sudden, sharp pain seems to act best. Chloroform burning is not available; but a sharp pinch of the skin of either leg or arm reinforces k.-j.

Heat. When heat is great enough to cause sudden pain it increases the k.-j., whenever used on arm, leg, or trunk, but as regards the face and neck in some persons it is efficient, and in others causes no response. The touch of a hot knife-blade on the thigh struck gives excellent results. If the heat used cover a large sensitive surface and is not great enough to cause pain, as when an assistant drops the passive hand of the subject into rather hot water, a good increase of k.-j. is observed.

Cold. Mild impressions of cold over limited surfaces cause no visible effect. The sudden application of water at 32° F. to the entire hand often strongly reinforces the k.-j., or a cold spray on leg, widely used. More remarkable are the effects of a jet of rhigolene spray on the skin of the thigh struck. At the moment of chill there is little effect; but when abruptly the part grows white and frozen, there is a momentary sharp painful sensation, and the k.-j. increases, and is exaggerated until the entire part thaws, after which, for a time, the k.-j. is below the normal of excitability. The same results may be had with rhigolene on the other leg, or either arm or hand. In one person, freezing of the neck or face, cheek, or temple, gave remarkable additions to the k.-j. In another, rhigolene freezing of the neck caused no obvious result.

Taste. Our experiments in this direction were limited to the effects of red pepper, salt, and vinegar on the k.-j.; the results were entirely negative.

Hearing and smell. No experiments were tried by exciting these senses.

Sight. When a magnesium wire is burned, and a succession of abrupt exposures of the eyes is made by moving a screen quickly to and fro, the first effects are not notable, but at the third or fourth, as the light becomes painful, there is a reinforcement of k.-j.

Effect on the knee-jerk of pressure on, and stimulation of the sciatic nerve. For some time we have noticed that if the thigh of the side to be investigated was supported by a staff, or by the arm being placed under it, so that the pressure came upon its middle third, the k.-j. was obtained with difficulty, or not at all. To investigate the cause of this, pressure was made upon the sciatic nerve in the middle third of the thigh with a tourniquet, for the period of fifteen minutes; this caused pain in the spot pressed upon, tingling, and, finally, numbness of the leg and foot.

During this experiment the k.-j. of the side experimented on rapidly diminished, until it could scarcely be obtained; while the k.-j. on the opposite leg remained unchanged. On several occasions, when the leg had gone to sleep from sitting in a cramped position, the k.-j. was tested, and always found to be less than that of the opposite leg.

These facts are curious, and rather at variance with some of our other experiments.

Even the encircling band produced by rolling up the pantaloons above the knee sometimes makes enough pressure to interfere materially with the k.-j.

To test the effect of direct stimulation of the sciatic nerve on the k.-j. a full-grown male rabbit was etherized, and the k.-j. found to be good; the sciatic of the opposite side was now carefully dissected out and severed from its muscular connections. Tetany of the extensor muscles of the untouched leg was now caused by taps on the tendon, and then the sciatic was stimulated by a current from a Du Bois-Reymond coil. With the coil as far out as thirty or twenty centimetres there was no appreciable effect on the k.-j., but with the coil at fifteen or ten centimetres there was a very marked reinforcement of k.j. This was verified over and over again, and the effect of the application was to make the k.j. more easily obtainable for some time afterward. The cord was then cut in the upper dorsal region, and the experiment was repeated with the same result. With the coil at five centimetres distance, the k.-j. was now evoked when the tap on the tendon was made with a thin piece of whalebone, so lightly as to cause not the slightest visible movement in the muscle.

Nitrite of amyl. The inhalation of nitrite of amyl carried to full flushing of the face appeared in no way to influence the k.-j.

Ether. Our experiments in this line were but few, and confined to animals. In dogs the k.-j. was not materially affected by light etherization after the first excitement stage was over, but full etherization entirely abolished it, and it was curious to witness the k.-j. come and go with the varying stages of anæsthesia. This was not so apparent in the rabbit.

(To be concluded.)

RESECTION OF THE LARGE INTESTINE FOR CARCINOMA.[1]

BY ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL; CLINICAL PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS.

THE resection of a portion of an intestine for disease of its coats has been performed in Europe some thirty-one times, but it is believed that the following case, the first successful one in this country, is sufficiently unique to justify me in asking the attention of this Society to a brief consideration of the subject. The details are as follows:

In October of last year, 1885, the patient, a tall, fully developed man of fifty-four years, was admitted to my wards in the New York Hospital, for the treatment of what he considered bleeding piles. He gave

[1] Read before the New York Surgical Society, January 26, 1886.

the history, that for two years past he had had daily six to ten bloody and painful passages from the bowels. During the tenesmus induced by these, there was at times a considerable prolapse of the rectum. There was found, by digital exploration of the rectum, one or two small quiescent internal hemorrhoids, and, in addition, at the distance of a finger's length, could be felt, obscurely, the lower surface of a hardened mass, which, under anæsthesia by ether, could, by bimanual examination, be outlined as an irregularly elongated mass, movable from one side of the belly to the other, and situated at the upper border of the pelvis. No pelvic or lumbar glands were found enlarged, nor was any visceral complication detected. The conclusion was arrived at, that it was tuberose carcinoma of the upper end of the rectum, inaccessible to operative procedures by the anus, but removable by laparotomy.

The condition of affairs, and the risks attendant upon such an operation, were laid before the patient, who was a man of unusual intelligence, and who, after deliberation, determined upon submitting to the operation. This was therefore done on October 22d, under full antiseptic precautions, and in the operating room of the hospital devoted to abdominal sections.[1]

The diet of the patient was restricted for forty-eight hours previously to semi-fluids such as milk, bread, and eggs. An enema induced defecation a few hours before the laparotomy, and the urine was passed just before the etherization. Under a carbolic spray (which, in certain operations involving the cavity of the abdomen or a joint, I still prefer), an incision four inches long was quickly made from one inch below the umbilicus downward, and the peritoneum reached, seized and lifted between two clamp forceps, opened, and divided to the full extent of the wound by straight scissors. The intestines, as was hoped, were undistended, and three fingers of the left hand were then carried into the peritoneal cavity, the tumor readily caught and drawn out of the belly wound after some depression of the abdominal walls, and surrounded by flat disinfected sponges. It was a knobbed mass four inches in length, and its upper edge reached nearly to the sigmoid flexure of the colon. Temporary ligatures of heavy, soft, sublimated silk were carried through the mesorectum, above and below the mass, and the intestine, for a distance of five and a half inches, including the tumor, cut off, and removed after tying off the mesorectum by several ligatures of silk parallel to the bowels, dividing it as far from the latter as possible. In the stump thus made after extraction of the neoplasm, were seen two small enlarged glands; these were dug out, and a further portion of the mesorectum cut away after being duly ligated.

The important point as to whether a reunion of the divided intestine should be had, was decided negatively, and the creation of an artificial anus determined on for the reason, that though the cut ends could be easily apposed, yet, in spite of all the care that might be exercised, leakage would be apt to occur. Reichel found this had happened in 31 instances out of his 121 collected cases of intestinal resection; in 13 of these it caused death, in the others, fecal fistulæ resulted.[1] Moreover, the junction would have to be made deep in the pelvis, some four and a half to five inches from the anus, where the safe suturing of the bowels was felt to be a matter of extreme doubtfulness.

This was fully verified when, after the above decision was acted upon, the inversion and closure of the lower end of the bowel were attempted. Great difficulty was encountered in placing the double row of serous sutures (Czerny-Lembert) after the preliminary suture of the mucous membrane, and a third row was required at the posterior part to effect a satisfactory dimpling in of the bowel. And lastly, the chance of local return of the growth influenced me in preferring the establishment of an artificial anus.

This was accordingly done by carrying the upper divided end of the gut into the superior angle of the wound and allowing it to protrude, so that the part encircled by the temporary ligature (which was then cut away and a few bleeding points secured) should be outside the peritoneal cavity, in the event of any ulceration from its transient constriction. It was there fastened by three or four sutures, and the abdominal wound, after a fresh inspection and testing by sponges had shown that the peritoneal toilet had been properly made, was closed by strong catgut sutures, first passed through the whole thickness of the belly wall, but not tied till afterward, then the peritoneum itself was brought together with a continued catgut suture, and lastly catgut was passed through the skin and muscle to the peritoneum. This method of closure has been found best to avoid the formation of mural abscesses, but does not entirely get rid of, I regret to say, the smaller stitch abscesses. A sublimated gauze dressing on which iodoform was dusted was applied to the wound, and over that a large mass of absorbent cotton and a firm body bandage.

From the time of the operation until the 27th Oct. (five days), the patient complained severely of pain on each side of the wound, with occasional hiccough, and during the last twenty-four hours increasing distention of the abdomen occurred. His pulse however ranged below 90, and the temperature was less than 100°. Two of the deep stitches were cut to ease the tension of the swelling and to relieve the commencing tympanites. An evacuation of the bowels was solicited by gently introducing through the artificial anus a soft rubber catheter and carrying in several ounces of warm water. No immediate effect resulted. He was therefore ordered the next morning to take two ounces of Hunyadi Water.

On Oct. 28th, on removing the dressing, as his bowels had moved painlessly under the action of the cathartic, it was found that the wound was open throughout its whole extent, and in the mass of feces filling it was seen a coil of small intestine. After carefully wiping away the feces it was per-

[1] This is a small special room with the walls rounding into the ceiling, thickly painted, so that all the room and its few contents can be washed previously to an operation with, first, soft soap and water; secondly, with a solution of sublimate, 1:1000; and then, thirdly, for two hours bathed with the fumes of burning sulphur.

[1] Deutsche Zeitschr. für Chirurgie, No. 19, 1884.

ceived, fortunately for the patient, that adhesions existed sufficiently to shut off the general peritoneal cavity, which fact allowed thorough cleansing and washing of the bowel, and its reposition in place, when the wound was sewn up with three wire sutures passing down to, but not through, the peritoneum, the adhesion of which to the intestines beneath rendered this latter impracticable and unnecessary. No reaction followed this mishap. The patient's general condition steadily improved, with evacuations from the bowel once or twice a day, which, in spite of the impermeable dressings contrived, so frequently entered the wound as to preclude secondary union, and its healing proceeded by granulation to completion in about seven weeks, with a firm, unyielding scar.

From November 4th to 13th: Though progressing favorably, he had occasional pain in the belly and slight temperature elevation, up to 101° at night, without sweating or chills, and very little pelvic tenderness.

On Nov. 14th I was informed that he had had during the previous night a fecal discharge from the anus. It had been thrown away by the nurse, but was reported as being of ordinary character and very soft. This was thought to have been mainly the contents of the rectum, left in at the time of the operation. On the 15th, considerable flatus was passed *per anum*, and on the 16th he discharged by the same orifice nearly a pint of dark brown fluid of a strongly fecal odor, greatly to his relief.

Speculation on the possible source of a fecal or flatulent discharge took several directions, two of which seemed probable. The first was, that during the last transfixion of the mesocolon by a doubly threaded needle, the point of this instrument had suddenly struck and torn an adjacent loop of small intestine, quite through to the mucous membrane. The slit was promptly sewn up by several Lembert sutures. This might have given way and discharged itself per rectum.

The second possibility was this: it was noticed after the second slice of the mesocolon had been removed, that the triangularity of this tissue had not been preserved, and that the portion of the bowel leading from the proposed artificial anus, for three inches, had a somewhat scanty mesentery. Its truncation to avoid gangrene from a defective blood-supply was discussed with my colleague, Dr. Bull, but on holding the mesocolon up to the light, the vessels going to it seemed to be large and numerous, and hence it was preserved entire. It was possible that a spot of gangrenous intestinal wall from this cause might thus have allowed a fecal extravasation to be conducted externally by the disused rectum.

No further discharge took place until November 20th, when two ounces of a thin, light brown, markedly purulent fluid were discharged *per anum*. On the introduction of the finger into the bowel the upper limit of it could not be felt, and a rubber drainage tube was thereupon passed in at least six inches, giving vent to three or four ounces of very fetid brownish pus. The tube was left *in situ* covered by sublimate gauze, and the next day, and daily thereafter, the abscess cavity was washed out through it, at first with a 1 : 5000 sublimate solution, and then 1 : 10,000, and finally, with Hey's solution (sulph. zinc, gr. ij; spts. lavand. co., ʒj; aquæ, ʒj). This discharge ceased in about three weeks. The rectal tube was worn ten days without discomfort.

It was evident that the above hypotheses were all wrong. The abscess, I think, was formed from some hemorrhage or from the stump enclosed by the silk ligatures, which made a mass uncovered by peritoneum, nearly two inches long, by three-quarters broad. This had been dusted by powdered iodoform before the abdomen was closed, and on reflecting on the operation, even before the disclosure of the abscess, it was felt that it would have been wiser surgery, in similar circumstances, to have left in a drainage tube. During the evacuation of this purulent collection the patient complained sorely of pain over his liver, and this was found to be enlarged. As the cessation of pus formation took place, the hepatic tenderness disappeared, though the increased dulness on percussion remained. Whether this signifies a secondary deposit in that organ, I cannot yet say, though I fear it may so culminate.

He left the hospital for his home, in Scranton, Pa., January 2, 1886, rapidly gaining in strength and flesh, and controlling the discharge from the artificial anus better by a simple plug of cotton or gauze secured by a strip of adhesive plaster, than by the many other expedients which were suggested, and in other cases successfully tried. The pathologist's report of the tumor pronounced it one of encephaloid cancer.

Remarks.—I have been able to collect thirty five cases in which excision of a cancerous intestine has been resorted to, and in all save one (Schede's) the disease has involved the large intestine; in an additional case (Credé's) the operation was abandoned, only a small piece being removed for microscopic examination. Of this number, it is to be noted that of the five cases[1] in which the operation was done during the exhaustion attendant upon an acute obstruction of the bowel, all died from the shock of the operation, hence this condition is considered by Schede to contraindicate the operation. Of these 33 cases (for in one, No. 18, the result is unknown) there was a mortality of 17, or 51.5 per cent., only a little greater than that which results from resection of the large intestine from other causes,[2] and which is given in Maydl's recent article on the subject at 50 per cent. Aside from the shock, ten died within forty-eight hours; in a number of cases, the progress was complicated by the escape of feces, as shown at the autopsy (four died from peritonitis from this cause), or by the presence of an intestinal fistula. When the latter occurred in the course of an otherwise favorably progressing case, it, as a rule, closed later spontaneously. This escape of the intestinal contents was due either to a faulty suturing, or to the minute gangrene so apt to take place from slight unperceived stripping up of the mesocolic attachments. For the sutures, silk or catgut was used, and though,

[1] Thiersch, Gussenbauer, Schede, Guyon, Treves.

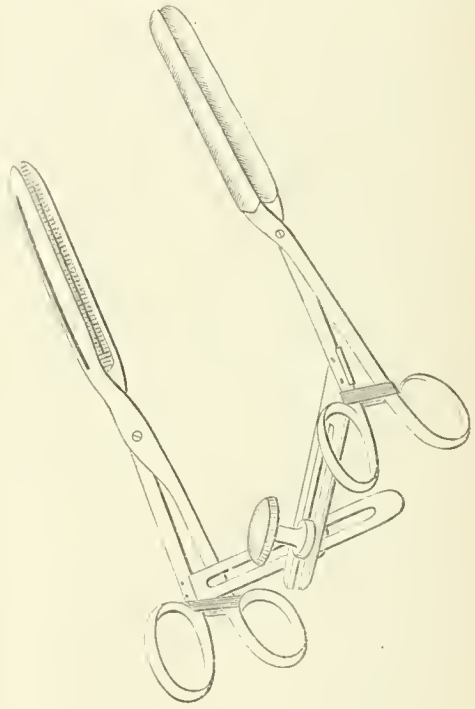
[2] In six resections, for two gangrenous herniæ, three prolapsed artificial anus, and one cicatricial stricture, there were three recoveries—Maydl: Beiträge zur Darmchirurgie, Wien. med. Zeitung, 41, 42, 43, 1885.

in the majority of cases the usual interrupted suturing of first the mucous membrane, and then the double rows of the peritoneum, known as the Czerny-Lembert suture, was resorted to, yet Schede, among others, recommends strongly the continued suture, one to the mucous membrane, and two to the serous coat (and, as he prefers, with sublimated gut), as amply sufficient, and, what is of more consequence in a prolonged operation such as this is, with the saving of one-half to three-quarters of an hour's time. This more careful closing of the opposed mucous membrane is also of service in preventing fecal extravasation between this and the muscular coat (Maydl).

With the possibility of such a mishap, after uniting the ends of the intestine, and especially in the case presented, where there is left much of an uncoverable subperitoneal surface, I would be strongly disposed to use hereafter, should an occasion offer itself, a glass or rubber drainage tube, to avert, if possible, the risk likely to arise. If it were, however, possible to keep the joined intestine after a resection outside the peritoneal cavity until union had taken place, the ideal would be fulfilled, and all risks from intestinal leakage would be obviated; but as this is difficult, from the kinking of the loop of bowel at the line of suture, and from its congestion by the constriction of the abdominal wound, Maydl has successfully carried out in his last cæcum extirpation, the suggestion[1] that the belly wound should be kept open after securing the peritoneum to the skin, and the united intestine held up to it by one or two loose sling sutures carried through the mesentery. The protrusion of intestinal coils was prevented by iodoform compresses placed in and over the wound until adhesions formed. This takes place rapidly, and both in Maydl's case and in my own the unintentional similar treatment of the wound has shown the feasibility of the plan.

The variation in the site of the incision in the abdominal wall, to revert to the *technique* of the operation in its proper order, was not great; usually, it was made in the median line. In resections of the cæcum and sigmoid flexure, Maydl and Billroth incised either parallel to Poupart's ligament, or from the umbilicus to the same ligament, or to the outside of the rectus and low down. For tumors of other parts, the mobility of the intestine permitted the use of the usual laparotomy section. Great difficulty was a few times felt from the considerable distention of the bowel, above the tumor; but in nearly all these instances it was possible, either by traction alone, or by combined depression of the abdominal walls, to bring the tumor outside the peritoneal cavity, where sometimes it could be shut from the latter by a partial temporary closure of the abdominal incision, or by carefully placed flat warm sponges or compresses of iodoform gauze. Where practicable, it has been found better first to tie off the mesocolon in small sections, and divide it from its attachments to the diseased intestine, and then to remove the portion of bowel determined on. Gussenbauer preferred to divide the intestine below and between a double ligature, and did not cut above the tumor until all the mesocolon was severed, but this plan has not been usually followed.

Whether the gut be divided prior to, or subsequent to the mesocolon, its ends have easiest, and most frequently, been secured by the various operators either by the fingers of an assistant, or by a not too tightly applied temporary ligature of silk, as in my own case, or what I judge the best so far, by tape-like strips of antiseptic gauze, such as have been employed by Billroth. Rydygier's clamp, which, it will be remembered, consists of two rods covered with rubber tubing, between which the intestine rests and is held compressed, by rubber bands encircling the ends of the rods, has been successfully used, but the clamp of Treves[1] has been abandoned by its author, in favor of Bishop's.



The latter instrument is too complicated, and of all the mechanical contrivances for the purpose, I would give the preference to that of Dr. Abbe, of this city, of which a diagram is annexed.[2] The blades of this instrument are covered with several layers of flannel, instead of rubber tubing, and thus afford a surer hold, and the compressing power at the handles is effected by thin bands of rubber. It also readily allows of a change of position, and rapid elongation and shortening. In passing the temporary ligatures, a spot in the mesocolon devoid of vessels can often be chosen, and is to be preferred.

After the removal of the diseased mass, a careful

[1] Reichel is opposed to this method of treatment, and says the sutured intestine should be fully returned, and the wound closed without a drainage tube, which is superfluous, as is also the fixation of the sutured gut.

[1] See diagrams in Treves on Intestinal Obstruction, pp. 481, 842.

[2] Manufactured by W. T. Ford, New York.

search should be made in the severed mesocolon for diseased glands, which can usually be easily removed. The question which then comes into the mind of the surgeon is, whether a reunion of the divided ends of the intestine, or an artificial anus with both ends in the wound if practicable, should be made. This point has already been touched upon in the narration of the case which forms the basis of this paper. In most of the cases in which recurrence was noticed, it took place locally, either renewing the stenosis by the involvement of the bowel itself, or producing the same through pressure from a growth in the parts adjacent. This reproduction of the neoplasm was observed in two cases in the site of the artificial anus, and admitted of partial relief by stretching, etc. The objection raised, that by waiting to perform a subsequent resection of the intestine for the false anus created by the first operation, an additional risk is run, is not so weighty as it at first seems, since the investigation of Reichel shows that in thirty-seven resections of the intestine for the relief of an artificial anus, only two deaths resulted. The fact that in the eight cases where an anus was thus produced, death resulted in five, should not be interpreted that this plan of action is necessarily a more fatal one than is resection of the bowel, for not only are the cases too few to dogmatize upon, but also in more than half of these instances the anus was made because the parts removed had been so extensive as to render impossible the union of the divided ends of the bowel, and the operation itself thereby rendered more hazardous.

The conclusion already stated is, therefore reiterated, that in an intestinal resection for a malignant neoplasm, it is wisest to establish an artificial anus.

Only a reference need be made in this connection to the lumbar incision for the removal of intestinal growths. This has only once been resorted to, with fatal result, by Lammiman, who, after taking away the tumor, brought out the lower end of the colon in the wound after placing a ligature around the lower end of the bowel, and dropped it in the abdominal cavity. Bryant's case, which preceded this, recovered. It was the result of the accidental opening of the colon in an ordinary colotomy immediately below the seat of the malignant stricture. This was detected and drawn out of the belly, and four inches cut off, and the two ends of the bowel fastened in the lumbar wound. I see but little to recommend in this procedure, as its scope must be confined to a very limited topographical region, though it has the endorsement of so excellent an authority as Treves.

A much more important consideration after all, is whether such hazardous operations are justified for the removal of malignant growths. In common with other surgeons, I feel the discouragement that attends endeavors to give relief, or to prolong life, and most remotely, to effect a cure in such conditions. The operation with which this more recent extirpation of abdominal growths has been compared, is lumbar colotomy, which is, however, merely a palliative one, and, according to the rich experience of Allingham, not effectual in prolonging life. Its risks, too, are, I think, made light of.

The large statistics of Erkelen,[1] embracing 262 cases of colotomy for all causes gave a mortality of 58.4 per cent., and for 110 cases of carcinoma 37.7 per cent. of deaths. The cases of recovery after resection of the intestine for a neoplasm, are too few to place with those of colotomy, and can only be fairly considered with the first cases of the allied operations of extirpation of the rectum and of the uterus by the vagina for cancer, both of which have now come, by increased experience, to have an acknowledged standing in surgery, and a diminished mortality from improved methods of operation, and judicious care in the selection of cases. To me, I confess, the fact that one can hope to have room enough in the intestine and mesentery to get wide of the tumor, is an advantage not possessed by any of the abdominal operations for malignant growths, except in ovariotomy, and in the belief that the dangers that come immediately from the operation can be more and more satisfactorily coped with, I venture to commend, in this brief paper, the resection of such intestinal tumors with, as a rule, the establishment of an artificial anus.

But a careful diagnosis must be made under ether to determine the mobility and freedom from adhesions of the growth, and the absence of pronounced glandular involvement. The interrogation of the organs, as, for example, the liver, in which secondary deposits are most likely to occur, should be strict, not only by palpation and percussion, but also by the newer corroborative chemical tests of urea diminution, and peptone increase, etc.

The operation should generally be begun as an exploratory one, with Tait's statement in mind, that it is harder to know when to desist than to go on. If the tumor is an unfit one for extirpation, an ordinary artificial anus can be made either in the exploration wound, or in the groin. This has been done, after Littré's plan, for carcinoma, in 23 cases, and has given a mortality of 39 per cent.[2]

I have appended a table comprising the collected cases. These are interesting in several points other than those touched on in the foregoing remarks. In respect to one—the recurrence, a few words may be added: in 10 of these, where the fact of recurrence is noted, it took place in 3 cases (Czerny, Kraussold, Billroth) in less than one year; in 4 others (Reybard, Maydl, Volkmann, Bryant) between one and two years; and in one case (Fischer's) over two years, and in Gussenbauer-Martini's case the patient was free from disease at the date of our last report, four years after the operation. In Schede's, where a laparotomy was unsuccessfully done for intestinal obstruction, nine months after the resection and reunion of the intestine for cancer no trace of the recurrence of the neoplasm was found, and the interesting point was also developed that the turning inward of bowel by the Czerny-Lembert sutures had not given rise to any permanent projection into the lumen of the gut, only a simple linear cicatrix being perceived.

TABLE OF RESECTIONS OF THE INTESTINE FOR MALIGNANT GROWTHS.

No.	Operator, and date.	Disease.	Length removed.	Treatment of resected intestine.	Situation, etc., of abdominal wound.	Result.	Where reported.
1	Reybard,[1] 1843.	Carcinoma of sigmoid flexure.	3 inches.	Sutured and returned.	6 inches long, above crest of ilium. Wound united by 3 sutures.	Recovery; 10th day movements from bowels. Recurrence 6 months later, and death 1 year after operation.	Bull. Acad. de Méd., t. ix. p. 1033.
2	Thiersch,[2] 1875.	Carcinoma; acute obstruction	Not stated.	Lembert's suture, intestine united and returned.	Linea alba.	Died in 12 hours, septic peritonitis.	Deutsche Gesellsch. f. Chir., 1878, Bd. vii. S. 127.
3	Gussenbauer, Dec. 6, 1877. Man.	Carcinoma of colon; adherent also to small intestine; acute obstruction.	3 inches.	Ends united by Lembert and Gussenbauer suture; wound accidentally made in small intestine closed by 3 sutures.	Linea alba, and a second one transverse to this.	Died 15 hours after operation, from collapse.	Archiv f. klin. Chirurg., 1878, Bd. xxiii. S. 233.
4	Schede.	Carcinoma of descending colon.	None removed; disease found too extensive; intestine cut off	Ends sutured to wound as they could not be approximated.	Over tumor on left side.	Died in 24 hours from inanition; no peritonitis.	Deutsche Gesellsch. f. Chir., 1878, S 126.
5	Billroth 1879. Woman, 60.	Carcinoma of descending colon at transverse flexure.	Not stated.	Enormous distention of bowels; artificial anus made, as it was impossible to unite ends, why not stated. Lower end closed and left in. To replace intestines incisions made to let out flatus, which were afterward sewn up.	.....	Died in 24 hours.	Hauer, Zeitsch. f. Heilkunde, 1884, S. 83.
6	Gussenbauer and Martini, Nov. 9, 1879.	Carcinoma of sigmoid flexure and mesocolon.	4 inches.	Lower end turned in on itself; sutured and returned to pelvis Upper end made an artificial anus in superior end of wound.	Over tumor in left side of abdomen.	Recovered; in 2 mos. resumed work. Reported by Schede in 1883 as still free from disease.	Petit, Bull. Gén. de Thérap., t. ciii. 486, from Zeitschr. für Heilkunde, Bd. i. S. 208.
7	Guyon, Nov. 23, 1879.	Cylindrical epithelioma at juncture sigmoid flexure and rectum.	2½ inches.	Ends united by 15 sutures, and bowel replaced.	Linea alba.	Movements followed immediately; died in 3½ hours.	Petit, Bull. Gén. de Thérap., t. ciii. 537, from Peyrot, De l'intervention chirurgicale dans les obstructions de l'intestines
8	Baum, Jan. 13, 1879.	Carcinoma of ascending colon. Fecal fistula made 8 weeks before operat'n above Poupart's lig. on right side in small intestine, to allow escape of gas, which prevented use of percussion and palpation.	3 inches.	End of upper intestine being longer than that of the lower end, the former was made smaller after Billroth and Czerny's method, a wedge-shaped piece directed outward being made by 6 stitches. Ends then united with carbolized silk, Gussenbauer's sutures. Gut returned.	Incision 3 inches long over tumor, 1 inch below ribs, 3 inches to right of median line. Supplementary incision 2 inches long from middle of first, running to right. Wound united with silk.	5th day soft movement died 9th day; no peritonitis: sutures gave way.	Centralblatt für Chirurg., 1878, vol. vi. p. 169.
9	Kraussold.	Carcinoma sigmoid flexure.	Not stated.	Sutured.	.....	Recovered; died 6 months later of recurrence in mesentery.	Sammlung klin. Vorträge, 191, S 1724.
10	Kraussold, April, 1879.	Carcinoma ileocæcal valve, cæcum, and verniform process.	.....	Joined by Lembert's sutures, silk.	As for ligation right external iliac.	Died of shock in 2 hours.	Centralblatt für Chirurg., 1881, vol. viii. p 186.

[1] The report of this case being made to the Academy of Medicine, it was referred to a committee made up of Blondin, A. Bérard, Jobert de Lamballe, to whom Reybard detailed his experiments upon dogs, previous to his operation. Seven dogs were operated upon by the commission, four surviving; but the committee sent in a report against the operative innovation of Reybard.

[2] In Thiersch's resection about a quart of fecal matter came out of distal end. When this appeared empty, he began to unite ends with Lembert's suture, and before he had finished a peristaltic movement forced a large amount of feces out, and a part entered abdominal cavity. He then made an artificial anus above the operation wound, allowing free exit to the feces, after which he finished suturing gut.

TABLE.—*Continued.*

No.	Operator, and date.	Disease.	Length removed.	Treatment of resected intestine.	Situation, etc., of abdominal wound	Result.	Where reported.
11	Czerny, 1880.	Carcinoma of transverse colon and sigmoid flexure.	3 inches of sigmoid flexure, and 4½ ins. of transverse colon.	Cut ends of sigmoid united by 33 sutures. colon by 26.	4⅓ inches long over tumor in left hypochondrium. United by deep and superficial sutures; drainage.	Recovered; movement 10th day after injection. Abdominal wound opened, and healed in 4 mos. but recurrence began and patient died at end 7 mos. 11 days.	Petit, from Berl. klin. Wochenschrift, 1880, 638.
12	Credé, 1880. Incomplete operation.	Carcinoma of intestine.	.....	Only a portion of tumor removed for microscopic examination; it was found to have many foci.	.....	Recovered.	Archiv f. klin. Chir., Bd. xx. S. 293.
13	Wittelshoefer (Billroth), July 1, 1880.	Carcinoma of sigmoid flexure.	9 inches.	Lower turned in and sutured, upper sutured to upper end of wound.	To left of median line with convexity extended. Sutured from below up to artificial anus.	Died in 14 hrs. from general peritonitis and endocarditis.	Wiener med. Woch., 1881, S. 185.
14	Fischer, Feb. 24, 1881.	Carcinoma of descending colon.	Nearly 3 inches.	United by Czerny's suture, and then fixed by a suture in lower end of abdominal wound.	Linea alba, upper ¾ closed, lower ¼ left open.	Movement 1 hr. after operation from rectum; 8th day feces came from abdominal wound, and fecal fistula formed here. Patient discharged on Oct. 19th (8 mos. after operation) cured, with no sinus. Since dead. (Schede, 1883)[1]	Centralblatt für Chirur., 1881, Bd. viii. S. 794.
15	Bryant, Sept. 10, 1881.	Alveolar carcinoma of descending colon	About 4 inches.	Upper end made into artificial anus; lower closed, and sewed to lower end of wound.	For left lumbar colotomy; stricture found above wound thus made, and pulled down, excised; lower part closed; upper made into art. anus.	Recovery; movements during operation. Aug. '82, doing well; there had appeared recurrence at opening 1 year later, which demanded stretching.	Medico-Chir. Trans., vol. lxv. p. 131.
16	Nicolaysen, March 1, 1881 Woman, 49.	Carcinoma, sigmoid flexure prolapsed beyond anus.	.....	While protruding beyond anus it was removed with its mesentery.	Removed per rectum.	Recovery; 2½ mos. later reported well.	Nord. Med. Ark., iv. No. 13. 1882, Centralb. f. Chir., No. 36, 1882.
17	Von Wahl, 1882? Woman, 26.	Colon adherent to cancer of ovary and infiltrated with neoplasm.	4 inches.	Colon sutured together, Gussenbauer, Lembert; clamp to hold end intestine.	....	Recovery; though recurrence took place in a month.	London Med. Record, Apr. 15, 1883.
18	Bergmann, 1882. Man, 40-50.	Carcinoma cæcum.	?	Cæcum and small intestine sutured together.	Median incision.	?	Oral communication from Dr. E. M. Culver, who witnessed the operation.
19	Billroth, Aug. 20, 1881. Man, 56.	Carcinoma cæcum.	Cæcum and part of ileum.	Colon reduced in size by 11 "occlusive" sutures, and then united to small intestine by 11 Wölfler and 19 Lembert sutures.	From umbilicus to middle of Poupart's ligament.	6th day stercoraceous vomiting; wound opened; cause not found; artific'l anus then made. Died; no autopsy.	Hauer Zeitschr. f. Heilkunde, 1884, S. 83.
20	Billroth, Oct. 18, 1881. Woman, 29.	Carcinoma both ovaries, involving intestine and bladder, both of which were resected.	5 inches.	Ends united by 5 Wölfler and 9 Lembert sutures and replaced; gut held by assistants.	Median line.	Recovered; bowels moved on 10th day.	" " "
21	Marshall, April 15, 1882.	Carcinoma descending colon	3½ ins.	Lower end cleaned with sol. zinc chloride, and sutured to skin wound by silk sutures through serous and muscular layers, and gut sutures through all 3 coats; lower end ligated with gut and fastened in wound.	Wound in median line closed with silk; lateral wound made artificial anus; first incision made in median line just below umbilicus to pubes; supplementary incision 3 inches long, parallel to last rib of left side, 1½ in. above crest of ilium.	Movement during operation. Died 3d day, diffuse suppuration.	Lancet, 1882, p. 721.

[1] Reichel, in Deutsche Zeitschrift für Chirurgie, No. 19, 1884, p. 251, reports that this patient presented herself at the clinic in Breslau, June 5, 1882, with recurrence at site of former fecal fistula. In removing this two coils of large intestine were found adherent to growth and to abdominal wall. It was thought unwise to resect these intestines, and after removing the recurrence in the abdominal wall, the wound was closed and united primarily. During October, November, and December, fecal fistulæ and abscess formed between umbilicus and symphysis, and patient died January 9, 1883.

TABLE.—*Concluded.*

No.	Operator, and date.	Disease.	Length removed	Treatment of resected intestine	Situation, etc., of abdominal wound.	Result.	Where reported.
22	Volkmann.	Carcinoma upper part sigmoid flexure.	4 inches.	Artificial anus made; both ends brought into wound.	?	Recovery; reported in 1884 as dead from a recurrence of cancer 1½ year after operation.	Centralblatt f. Chir., No. 10, 1883
23	Maydl, April 1. 1883. Man, 54.	Cancer cæcum.	Cæcum and small intestine removed, 7 ins. in all.	Artificial anus made, and 6 months later closed by reuniting intestine after a further resection of 2 inches.	Outside of rectus; drainage after resection of fecal fistula, which slowly contracted, but did not heal.	Recovered, though since dead from recurrence 1 yr. later.	Wiener med. Presse, April, 1883.
24	Czerny.	Carcinoma cæcum and part of duodenum.	.....	.....	.....	Died.	Centralblatt f. Chir., No. 30, 1883.
25	Schede, June, 1883. Man, 50.	Carcinoma of small intestine attached to abdominal walls, tumor size of man's fist.	8 inches, mesenteric glands also removed.	Temporary ligature, ends united by single mucous and double row of serous sutures, all continuous and of sublimated catgut.	Median laparotomy.	Recovered; movement from 1st day; 9 mos. later intestinal obstruction from a band; laparotomy; death; no recurrence found.	Beilage zum Centralblatt f. Chirurg., 1883, p. 66.
26	Partsch, July 14, 1883.	Carcinoma of small intestine	3½ ins.	Sutured with silk passing through serous and muscular coats to middle of wound; ligature left about lower end of gut when stitched to wound.	From umbilicus to symphysis closed, except for 2 inches in centre, where peritoneum was sutured to edge of wound, and both ends of gut were secured.	During operat'n movements carefully kept from abdominal cavity; doing well on 4th day, except delirium, in which patient jumped out of bed and tried to escape; death 5th day, exhaustion.	Centralblatt für Chirurg., 1883, No. 52, S. 833.
27	Lammiman, Feb. 14, 1883.	Scirrhous carcinoma of descending colon	Not stated.	Upper end sutured to wound; lower end ligated with carbolized silk; gut returned to cavity.	As for left lumbar colotomy; closed to artificial anus.	Died in 48 hours from exhaustion; movement in a few hours.	Lancet, 1883, Aug. 4, p. 182.
28	Treves.	Cylindrical epithelioma of descending colon.	Not stated	Ends united by 25 Lembert sutures, not including serous membranes; uses Chinese twist silk; divides mesentery from the gut.	Median line.	Died in 12 hours without stool, from shock and exhaustion.	Med. Chir. Tr., 1883, vol. lxvi. p. 55.
29	Billroth, Jan. 28, 1883. Woman, 56.	Carcinoma of transverse colon.	6 inches.	9 inner and 27 Lembert sutures; tumor adherent to anterior abdominal wall.	Drain used.	7th, fecal fistula developed, which closed on 14th day; recovered; reported herself well 10 months later.	Hauer. Zeitschr. f. Heilkunde, 1883, S. 83.
30	Billroth, Mar. 23, 1884. Man, 55.	Carcinoma of cæcum size of apple.	2¾ ins. of colon, 1½ ins small intestine excised, after tying intestine tempor'rily with broad strips iodoform gauze	Ends joined with 22 sutures.	6 inches long, just outside right linea alba; drain used for 5days.	Recovered; 6th day bowels moved.	" " "
31	Sydney Jones, May 23, 1884.	Scirrhous carcinoma of ascending and transverse colon.	Not stated	14 silk sutures through whole thickness of gut joining ends; "others" through serous coat alone, one fastening serous coat to abdom. wall.	Over tumor 5 inches; vertical direction; closed, except in centre, here packed with gauze (iodoform).	Died 3d dy. No movement; exhaustion; no peritonitis, but "dirty looking pus had infiltrated tissues" at juncture of mesentery and gut.	Lancet, Jan. 10, 1885. p. 60.
32	Hofmokl, April, 1885. Woman, 24.	Malignant adenosarcoma of cæcum.	9½ ins. ends secured with 3 rows sutures: drained	Curved 5 inches from rectus, exposing tumor.	.....	Recovery; movements 5th day.	Anzeige der k. k. Gesellschaft der Aertze in Wien, May 1, 1885.
33	Lange, 1885.	Carcinoma of flexure and ascending colon.	4 inches.	Ends united with difficulty; duodenum wounded and sewn up.	.....	Died 2d day.	Oral communication in discussion on this paper.
34	Lange, 1885. Woman, 32.	Sarcoma of transverse colon, with sarcoma of both ovaries.	6 inches.	Ends sutured by Czerny-Lembert method.	Median.	Died 9th day from perforative peritonitis; diarrhœa persisting from time of operation.	" " "
35	Weir, Oct. 22, 1885. Man, 54.	Carcinoma of sigmoid flexure, lower end.	5½ ins	Temporary ligatures; artificial anus made; rectal end closed.	4 inches; median.	Recovery; left hospital Jan. 3, 1886, gaining flesh and strength; recurrence probable	This paper.

ANOMALOUS LOBATION OF THE HUMAN LUNG.

BY D. S. LAMB, A.M., M.D.
OF WASHINGTON, D. C.

AN article by Dr. Wm. A. Edwards, entitled "An Anomalous Human Lung, having Four Lobes on the Right Side," published in *The American Journal of the Medical Sciences* for July, 1885, has led me to look over my record of necroscopies; and I note the following anomalies observed in the lobation of the lungs:

January 10, 1866: Man, aged 25, colored. Left lung composed of three distinct lobes.

April 13, 1866: Man, aged 26, colored. Right lung composed of but two lobes.

May 5, 1866: Girl, aged 10, colored. Left lung composed of three lobes, distinctly marked.

June 18, 1867: Man, aged 45, white. Right lung contained an imperfectly formed middle lobe.

May 1, 1874: Man, aged 64, white. Right lung contained an upper and lower lobe, and two irregularly formed middle lobes.

November 6, 1881: Girl, aged 15, mulatto. Several congenital fissures of left lung

November 20, 1881: Man, aged about 40, white. Left lung contained three lobes.

March 29, 1882: Woman, aged 25, mulatto. Right lung; rudimentary additional lobe derived from lower lobe.

April 3, 1882: Man, aged 48, mulatto. Right lung contains but two lobes, and a white line marking out the third.

November 5, 1882: Boy, aged 19, mulatto. Right lung; middle lobe imperfectly separated from lower by line of thick connective tissue.

October 25, 1883: Man, aged 40, colored. Left lung; subdivision into lobes incomplete.

January 26, 1884: Woman, aged 25, mulatto. Right lung consisted of two lobes.

November 5, 1885: Man, aged 75, negro. Right lung; four lobes, two middle ones.

An analysis of these thirteen cases shows that the anomalies were found in nine males and four females; ten colored and three white. In 100 consecutive examinations there were about 60 males to 40 females; and 70 colored to 30 white. The anomalies were, therefore, relatively more frequent in the male sex and colored race. The number, however, is too small to warrant generalization; and besides, some of the bodies were as much *white* as *black*.

In five cases the right lung consisted of two lobes. In two of these the middle lobe was marked by a *line* of connective tissue, uniting it with the lower lobe; and in a third the condition may have been similar, the note made being that the middle lobe was imperfectly formed.

In three cases the right lung presented four lobes. In two of these there were two middle lobes. I recollect that in one the two middle lobes were side by side. In the third case the additional lobe was derived from the lower lobe.

In three cases the left lung showed three distinct lobes.

In one the left lung presented multiple fissures.

In one, the left lung, the subdivision into lobes was incomplete.

The record does not state, and I do not now remember, the relation of the primary bronchi or bloodvessels to the number of lobes. I have, however, attached less importance to an inquiry in this direction, because in so many of the lower animals there is, apparently, no law bearing on this point, at least as to the bronchi. As an instance, the dolphin, Delphinus Delphis, shows two primary bronchi going to the right lung, which is not lobed at all. Aeby, in his *Der Bronchialbaum*, etc., Leipzig, 1880, Tafel 2, Fig. 3, shows this well; and a specimen of the same came under my notice only a few weeks since.

ARMY MEDICAL MUSEUM, WASHINGTON, D. C.

MEDICAL PROGRESS.

LOCAL SEDATIVE FOR TEETHING OF INFANCY.—BOUCHUT recommends the following formula for use in painful dentition:

R.—Cocaine muriate	1 part.
Sodium borate	1 "
Syrup of marshmallows	20 parts.
Syrup of poppies	10 " —M.

S. Gently rub the gums with the syrup four times daily.—*L'Union Médicale*, Jan. 9, 1886.

A NEW SPIRILLUM.—At the last meeting of the Medical and Physical Society of Bombay, held September 4, the President, Dr. H. V. Carter, showed specimens of a new spirillum (or spirochæta) which he had found in the blood of an Indian rat. The organism is minute, yet of characteristic aspect and activity; so far as yet learned, its occurrence in the blood does not produce recurring pyrexia or other peculiar symptom.—*Indian Medical Gazette*, December, 1885.

ANTHRAX VACCINATION IN RUSSIA, hitherto unsuccessful, has at last produced satisfactory results. ZENKOWSKI, of Charkow, has vaccinated over 1300 sheep, with a resultant immunity which is apparently complete. In the presence of a number of Government and University officials, thirty of these vaccinated sheep were inoculated with a strong anthrax culture. The temperature rose nearly two degrees, to regain the normal on the fourth day, with entire recovery. In the control experiments, out of ten similarly treated unvaccinated sheep, eight died in from twenty to forty hours, and the ninth in six days.—*Centralb. f. d. med. Wiss.*, Jan. 2, 1886.

TUBERCLE BACILLI IN THE PUS OF OTORRHŒA.—NATHAN has examined the pus of forty cases of otorrhœa placed at his disposal by Prof. Bezold. In twelve of these he found bacilli of tuberculosis. Amongst forty-six preparations these were demonstrable in forty. Other traces of pulmonary tuberculosis corroborated these results in eight of the twelve cases. Physical examination revealed no pulmonary affection in the ninth case, that of a scrofulous child. The remaining three were subjects of caries; one suffered from a sequestrum in the mastoid, and caries of the ossicles existed in the other two cases. The other twenty cases, in which an examination revealed no bacilli, embraced various diseases; in three there was disease of the adjacent

cells, and perforation of Shrapnell's membrane. The presence of bacilli in the aural discharge of those patients also presenting pronounced pulmonary complications, places beyond doubt the phthisical nature of the middle ear trouble. It further exerts a determining influence upon the prognosis of these cases.—*Archives of Otology*, 1885, No. 3.

ALBUMINURIA CONSEQUENT UPON LESIONS OF THE SKIN.—AUGAGNEUR records several cases confirmatory of the well-known assumption that renal inflammation may be induced by suppurative lesions of the skin. The condition of the kidney is determined by the absorption of bacteria from the cutaneous lesion, or, as suggested by Fürbinger, by an absorption of the products of the retrograde metamorphosis of albumen induced by bacteria. Augagneur concludes, from his observations, that such renal inflammation usually subsides with the healing of the cutaneous lesions, and that its prophylaxis is best effected by antiseptic treatment of the skin trouble.—*Centralbl. f. klin. Med.*, Jan. 16, 1886.

THE PHARMACEUTICAL AND THERAPEUTIC USES OF ALGIN.—MR. WATSON SMITH calls the attention of pharmacists and physicians to a new product, *algin*, discovered by Stanford. It is a residual product of the wet way of obtaining iodine from certain marine algæ, being a nitrogenous principle, closely resembling albumen except in not being coagulated by heat. It forms perfectly definite *alginates* with metals. The alkaline and earthy-alkaline alginates are soluble, but the others are insoluble. The double alginates are easy of preparation, and almost all of them are soluble. Besides possessing many curious chemical properties, giving promise of extensive applicability in pharmaceutical and other processes, algin has a notable alimentary value, and may be advantageously substituted for gum-arabic in the preparation of a great number of dietetic and medicinal products.—*Physician and Surgeon*, January, 1886.

NEW PURGATIVES.—At a recent meeting of the Academie de Médecine, DR. DESNOS presented observations on baptisin, sanguinarin, juglandin, and phytolaccin. The last named he regarded as of especial interest, as it was found to be a reliable purgative in doses of from one and a half to three grains. It also possesses cholagogue properties. Sanguinarin was found to be unreliable, and its rejection was advised.—*Les Nouveaux Remèdes*, Jan. 1, 1886.

IRRIGATIONS OF ETHER IN THE VOMITING OF PREGNANCY.—In the *St. Louis Courier* we read of a young woman, primipara, of feeble constitution, who had vomited from the second month of pregnancy. At the end of the fifth month the vomiting became so violent as to threaten death, there being syncope, absolute prostration of power, noises in the ears, chills, cold, and profuse sweats, frequent and filiform pulse, etc. In their turn antispasmodics had been used (ether, valerian, musk), then opiates, carbonated and iced drinks, iodine externally and internally, blisters upon the epigastrium, hypodermatic injections of morphia—in fact, every known means of arresting vomiting—all without avail. It was suggested to try irrigations of ether upon the epigastrium. The effect was instantaneous; a single irrigation sufficed to cut short the vomiting. The patient drew a few long breaths, and said she was cured and felt perfectly well. The vomiting returned twice, subsequently, and each time ether irrigations arrested the trouble.—*Kansas City Medical Index*, Jan. 1886.

RAYNAUD'S DISEASE.—*The Journal of Nervous and Mental Disease* for Jan. 1886, gives the following *résumé* of four cases of Raynaud's disease. Dr. Colcott Fox has reported two cases of this disease to the Clinical Society of London. A woman, æt. forty-one, of extremely nervous temperament, dated her disorder ten years back, but she had probably had slight attacks some years previously. In the earlier stages all her fingers continually went "like white wax." This condition of recurrent local syncope gradually gave place to local asphyxia, and the feet became involved. The fingers gradually lapsed into a state of chronic asphyxia, which was intensified by frequent attacks of more severity, often leading to "blood-blisters" and ulceration. The nutrition of the phalanges suffered greatly, her hands being crippled, the fingers fusiform in shape, livid, shiny, and withered, the nails variously distorted, and the end phalanges much atrophied and almost immovable. The nose and ears become affected to some extent on exposure. Cold and nerve shocks are exciting influences. The second case, that of a male, æt. fifty-one, like one of Raynaud's cases, had diabetes. His hands were deformed, and he had suffered for several years with "dead fingers." He sought Dr. Fox's advice for symmetrical gangrenous patches on the skin, which recurred, and later for an attack of asphyxia of one great toe and lower third of the inner side of the leg, and then it was found that the other toe had been affected even more severely. On another occasion blood-blisters had formed beneath the ends of his toes.

Dr. Frank R. Fry, of St. Louis, also reports two cases. 1. A female, æt. thirty-two, had been under observation far two and a half years, having suffered from extreme general anæmia—or spanæmia—also uræmia, metrorrhagia, and great debility. Her heart was weak and irritable. She gave a syphilitic history. The symptom indicative of Raynaud's disease was the apparently bloodless condition of her hands. From the tips of the fingers to the wrists they had a bluish-white color, and the feel could only be described as cadaveric. She complained of an almost constant aching in them. The feet were in a somewhat similar condition, ischæmia not being so extensive as in the hands. This attack lasted for a week; later she improved, the attacks becoming less severe and less frequent. 2. Male, æt. seventeen; when first seen all the fingers of both hands back to the metacarpo-phalangeal joint were in an asphyxiated condition, apparently bloodless, cold, and stiff. He moved and used his hands in a clumsy manner as if they were stiff from cold. Sensibility was much obtunded, though pain accompanied and followed this condition. His attacks had commenced about one year previous. They occur from one to three times a day, and last from fifteen minutes to an hour. Nothing abnormal was found, except a slight irregularity and feebleness of the heart.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

PHILADELPHIA.

SATURDAY, FEBRUARY 13, 1886.

EXPERIMENTAL ENDOCARDITIS.

IN THE MEDICAL NEWS of October 24th, we referred to the observations of Orth, who was able to induce acute endocarditis by lacerating the valves and subsequently injecting microörganisms into the blood. An ulcerative process was in this way set up in the torn segments which could not be produced by the laceration alone or by simply injecting a fluid containing microörganisms.

RIBBERT, of Bonn, has published in *Fortschritte der Medicin*, No. 1, 1886, an interesting account of a series of experiments on myo- and endocarditis, both of which conditions he has been able to induce by injecting the staphylococcus into the blood of rabbits without any previous laceration of the valves. Cultures on potato were used for injection, and it was found that if the material was too finely divided or if too small an amount was injected, the effect was not so likely to be produced as when coarser particles were employed. The quantity introduced had an important influence. Less than a sixth part of a Pravaz syringe never produced endocarditis, though the animal would die in from two to three days. Half a syringeful of the coarser emulsion was invariably followed by adhesion and growth of the micrococci on the mitral and tricuspid segments, most frequently on the former. The aortic and pulmonary valves were never affected. The colonies formed either a continuous layer or were in scattered groups one or two millimetres in diameter. The free borders of the valves and contiguous parts of the tendinous cords were the regions most often affected. The histological examination of the valves showed very clearly the various stages in the process of destruction of the tissue and confirmed the views of Klebs and others that the micrococci first settle on the endothelium and penetrate in this way, and not from within, by embolism, as Köster supposes. The earliest change seems to be superficial necrosis, caused by the direct action of the microörganisms, to which succeeds rapidly an inflammatory reaction indicated by the presence of numerous leucocytes. The micrococci penetrate into the tissue and cause widespread necrotic destruction. Fibrin separates upon the masses, and we have in this way produced the characteristic fungoid vegetations of ulcerative endocarditis.

Cultures proved that the microörganism was the golden staphylococcus which has been shown by several observers to be concerned in certain cases of ulcerative endocarditis in man. To complete the evidence, we now require carefully prepared cultures from a case in man and a similar series of experiments to those undertaken by Ribbert. Doubtless such will be forthcoming at an early date, and will conclude, so far as possible, the experimental evidence of the mycotic character of malignant endocarditis. A further series of observations will be necessary to determine whether there are not, as has been suggested, various microörganisms capable of inducing endocarditis.

COLECTOMY FOR CARCINOMA.

IN the current number of THE MEDICAL NEWS, DR. WEIR records a case of successful resection of the sigmoid flexure of the colon, the patient being alive ten weeks and a half after the performance of the operation, with a probability of recurrence of the malignant disease. As the safe approximation of the divided ends of the bowel would have been a matter of great difficulty, an artificial anus was established by suturing the upper end of the gut to the superior angle of the abdominal wound.

In connection with his case, Dr. Weir tabulates thirty-five examples of excision of a portion of the intestine for carcinoma, in four of which the small intestine was involved, and in one of which the result of the operation is unknown. Excluding those cases, and adding two additional instances of which we have notes—the transverse colon being affected in one, and the sigmoid flexure in the other—three are on record at least thirty-two examples of colectomy for carcinoma. With this experience before us, the questions which naturally arise are, first, whether the operation should be undertaken at all, and, secondly, whether it is better, after the resection of the gut, to suture and return the ends, or establish an artificial anus.

That the operation is a most serious one is shown by the direct mortality of fifty per cent., sixteen of the thirty-two patients having died, and an equal number having recovered. Of the sixteen cases of

recovery, six are reported a few weeks after the performance of the operation, thereby leaving ten cases in which the final result is known. In seven of these the patients died of recurrence in from six to twenty-four months, or in eight months on an average; two were living with recurrence; and one remained well for four years. Hence, fifty per cent. of the patients die from the operation; the disease recurs in ninety per cent.; and a cure is effected in less than four per cent. In view of these results, the operation has certainly proved to be a most unpromising one.

Should, however, an operation be decided upon, the disposal of the divided ends of the bowel is a matter of serious consideration. Of twenty-four cases in which the gut was sutured and returned, eleven, or 46.8 per cent., perished; while in eight in which an artificial anus was formed, five, or 62.5 per cent. died. The evidence seems, therefore, to be in favor of colectomy and enterorrhaphy, but, as Weir points out, in one-half of the cases of the establishment of an artificial anus, that procedure was resorted to because so much of the bowel had been removed as to render it impossible to approximate the divided ends, through which the operation was rendered more hazardous. Suturing and dropping the gut is undoubtedly the more tedious procedure, and requires greater attention to details, and, in addition, escape of the intestinal contents into the peritoneal cavity is very liable to occur unless the stitches are inserted with the greatest care. For these reasons, we agree with Weir that it is wiser to establish an artificial anus.

DREAMS.

WHEN Shakespeare put into the mouth of Prospero, "We are such stuff as dreams are made of," he suggested no explanation of dreaming. He was simply teaching the vanity of earthly things; they were as unsubstantial, as perishing, as evanescent as are the visions that come to mortals in the night, when tired nature is receiving rest and restoration in sleep.

Few there are who do not have the companionship of dreams, or at least their occasional visits, from childhood to extreme old age; even the infant sometimes dreams, at least we have as certain proof of this fact independently of what the poets have told us, as we have of the dreaming of animals, which has been so strongly presented by the late DR. LINDSAY in his interesting work upon *Mind in the Lower Animals*. Prominent among the animals which dream he placed the dog, a truth that has been generally received from the time of Lucretius and of Seneca to that of Tennyson, whose line, "Like a dog he hunts in dreams," is familiar to all, though really the thought seems borrowed from the words of Ennius, *Et canis in somnis leporis vestigia latrat*. The starving have dreamt of costly and abundant viands, the poor have for a brief time revelled in exhaustless wealth, the neglected maiden may be the heroine of a more marvellous history than that of Cinderella, and the humble and lowly have become the possessors of thrones and kingdoms. Strange and magnificent processions may come to the closed eyes, and scenes apparently unconnected and often incongruous, but beautiful, may move before them like a swift panorama; the laws of time and space are set aside—Huber, the great naturalist, at sixty-six years of age, blind since he was eighteen, dreamt of seeing the sunshine, and once again with his own eyes, and not with those of another, beheld the beauty of nature as he did in boyhood. Once more those in distant lands return, and talk with us face to face; yea, even the dead come back, we again hear loved voices that have been silent in the grave for years, and behold loved forms that have long since yielded to nature's inevitable law, "dust to dust, ashes to ashes."

Dreams of terror and pain also come, of a peril which yawns for us on sea or land, of a wave that is just about to overwhelm us, or of falling from some dizzy height to a fathomless abyss; of being involuntarily driven to the commission of crime, or impetuously fleeing from it, not knowing where we shall go; or again, of a deadly danger when the tongue is speechless to call for help, and the hand cannot be raised for defence, and the feet refuse to carry us away; we suddenly waken in our agony and rejoice to find we were only dreaming, but will not trust ourselves to sleep again lest the terrors should return.

The subject of dreams is thus an interesting one to all. In its consideration we enter into the borderland lying between science and mystery, if not between matter and spirit, a land, however, into which science slowly but surely enters, shedding new light, though possibly she may never be able to solve all mysteries.

Nor is the subject of dreams without special interest to the physician, for they may be caused by disorder of important functions, or be the forerunners of grave disease; the hallucinations of dreams, usually dissipated upon waking, may become fixed in the mind, and lead to grave crime or confirmed insanity. Moreover, the physician who would know man not merely physically but psychically, must study not alone the psychology of waking, but also that of sleeping hours.

Laying aside those instances recorded in sacred history where dreams were Divine revelations of duty or prophecies of future events, because not belonging to general human experience, remote from our day, and not on the plane of human investigation, some dreams at least were regarded by the wisest of ancient philosophers as supernatural in origin. Socrates, for

example, if we can trust the word of Plato, had this faith, and his action was in certain cases determined by the revelations made in dreams, as one may readily see by referring to the *Phædo* and the *Crito*. Yet Plato has very clearly shown, in a passage in the *Republic*, that evil dreams may result from a disordered condition of the body: they come, he says, "when the wild beast in our nature, gorged with meat or drink, starts up and leaps about, and seeks to go and satisfy his desires." And, again, he says, "There is a latent wild beast nature, which peers out in sleep." Burton, in the *Anatomy of Melancholy*, while referring to "imaginary dreams, which are of various kinds, natural, divine, demoniacal, etc.," also states that they vary "according to humors, diet, action, objects, etc." Thus, while the supernatural element was recognized in some dreams by both Socrates and Burton, the latter, as well as Plato, asserted that other dreams were dependent upon physical conditions of the dreamer.

One striking fact in regard to dreams is their complete independence of the will. That this independence should exist in the evolution of dreams is, of course, not at all surprising, but that it should also exist as to their genesis does seem somewhat inconsistent when we compare the condition with the control that each one possesses in a greater or less degree over his sleep. We can will to waken at a particular hour, and generally succeed; thus one who retires at night having it strongly impressed that he must rise at a special time, in order to start on a journey, for example, generally wakens at that time—intense preoccupation prevents, probably, his sleeping as soundly as usual, and the will maintains a partial power. The mother wakens at the least cry from her sick child, or the nurse at a slight movement by her patient, and in each probably the wakening is in part volitional. But it is impossible for us to choose the subjects of our dreams. We may wish most strongly that some theme which has engaged our waking thoughts may be presented in sleep for involuntary mental action, or we may wish to see in these visions of the night a distant or dead friend, but our wills are powerless to gratify our desires. The late Sir William Hamilton justly remarked that it is not always the subjects that occupy us most when awake, that form the matter of our dreams; and it is curious that the persons dearest to us are precisely those about whom we dream most rarely.

While in some cases we can trace dreams to certain physical conditions, yet in most the connection is through too wide a series of associations, or otherwise so obscure that we cannot apprehend it.

In illustration of the former statement, we may refer to the incident narrated by the great metaphysician Reid, as occurring in his own case. He states, "I had got my head blistered from a fall. A plaster, which was put on it after the blister, pained me excessively for a whole night. In the morning I slept a little, and dreamed, very distinctly, that I had fallen into the hands of a party of Indians, and was scalped." In Dr. Reid's case the profound sensation aroused by the pain upon the external part of the head would very naturally suggest the character of the dream, while the dreaming probably was caused by the increased quantity of blood in the brain resulting from the fall. In the case of a woman the membranes of whose brain were exposed by very extensive destruction of the cranial bones, it was observed that during active dreaming the brain became elevated so as to make a slight projection through the opening; the case was under the care of Langlet, and is referred to by Tourdes in the *Dictionnaire Encyclopédique des Sciences Médicales*.

It is probable that dreams are prevented by profound sleep and they do not, as a rule, come in the first hours of rest, but rather when nature's forces have been partially restored, and the sleep is lighter. It certainly ought to startle us into wise thought and action, and right desires and affections, if it be true that the record of our rational lives is registered upon the pages of the brain, and that "every act of sentiment, of thought, of volition, has impressed in us a trace which may reappear." Sometimes, indeed, memory possesses unwonted power in sleep, and we may then recall facts which we vainly sought when awake. So, too, but also only exceptionally, dreams may bring solutions for problems which baffled hard, wakeful labor, and an eloquent passage or graphic description may come to the orator's mind while he is sleeping, or musical verses, as those of "Kubla Khan" to Coleridge, may be suggested to the poet in his dreaming. Such unconscious exercise of intellectual power is very rare, and possibly can only occur in a person of remarkable delicacy and perfection of brain structure, such a one as De Quincey described Charles Lamb to be; "the sensibility of his organization was so exquisite that effects which travel by separate stages with most other men, in his, flash along the nerves with the velocity of light."

We have been led into these observations by reading the very interesting chapter upon "Sleep and Dreaming," in Wundt's *Elémens de Physiologie Psychologique*. The author gives the fullest scientific account of dreams with which we have met, and we desire to present some of his explanations and conclusions to our readers, but having already occupied so much space we must defer this presentation to a future issue.

A NEW LOCAL ANÆSTHETIC.

AT a recent meeting of the Medical Society of Berlin, DR. LEWIN presented a most interesting series of observations upon the physiological effects of a

resinous extract obtained from the root of *piper methysticum*, which is soluble in alcohol, possesses a somewhat aromatic taste, and leaves upon the tongue a sensation of pricking and burning, soon lost in the supervening local insensibility. When the extract, even in very small amount, is instilled into the eye of an animal, a slight local irritation is evidenced by repeated blinking, which soon yields to a marked, enduring, and complete insensibility of the conjunctiva and cornea. In guinea-pigs Lewin has seen this insensibility continue for more than an hour, normal sensation gradually returning. The iris retains throughout its reflex responsiveness to optic stimuli. No anatomical lesions of the cornea or conjunctiva were observed as the result of its application.

When the solution of the extract is injected hypodermatically, the tissues with which it comes in contact completely cease to respond to the application of thermic, electric, and chemical stimuli—a transitory condition which is followed by no symptoms of inflammation.

In regard to the constitutional effects produced by the drug, upon man, much the same claims are put forward as in the case of coca. When used in moderate amounts, a feeling of comfort, contentment, and rest, with complete retention of consciousness and reason, is said to result. With large doses there is a sensation of dreamy happiness, with an intense desire for sleep; while in excess the infusion causes nausea, headache, paresis of the extremities, nervous trembling, and somnolence. The general effect upon birds, rabbits, and cats is analogous to that produced in man.

It is evident that the drug is of considerable importance, and, if further experience shows that it effects in man the prolonged local anæsthesia that it induces in animals, it will be of great utility in very many operations in minor surgery. A quantity of the extract has just been received, and in an early issue of The Medical News we will lay before our readers a report upon its properties.

PAINLESS SLAUGHTERING OF ANIMALS.

Some thousands of dollars, we believe, have been spent by the Antivivisection Society of this city for the purpose of suppressing scientific cruelties which do not exist, and we sincerely trust that the humanitarians who, in this impracticable way, have found vent for their superfluous money and energy, may be induced to turn their forces into a more worthy channel.

We would call the attention of our readers to the accounts appearing in another column concerning the unnecessary brutality which accompanies the slaughtering of animals in Philadelphia.

The committee appointed by the President of the College of Physicians is charged with the duty of endeavoring to secure the introduction of more humane methods into slaughter houses, and is composed of well-known vivisectionists. If they succeed in bringing about the proper reform, they will have done more for the relief of animal suffering than the host of antivivisectionists who have been clamoring for these many years.

There is one aspect of the matter which is of direct practical importance to the meat-eaters of Philadelphia, namely, the apparent total lack of any supervision as to the quality of the meat which is served upon the private tables, and perhaps more freely in boarding-houses. It is doubtful as to how far it is really injurious to eat diseased meat which is thoroughly cooked. We remember once hearing Prof. Leidy, in a lecture, state that on a certain day after dining feeely upon an unfortunate chicken, he called the cook and asked her why she had not sent in the liver, which tidbit he had in vain diligently searched for. The heroine of the kitchen replied, "the liver looked so queer I did not like to cook it." The Doctor then sent for it, and, taking it into his study, soon found that it was in the last stage of cancerous degeneration. Although the danger of physical ills may not be great from such ingesta when well cooked, sentiment is opposed to dining upon the products of disease. It must also be remembered that the poorest quality of beef is usually made into sausages, and that many of these so-called bolognas are eaten raw, or only partially cooked. If there be any truth whatever in the doctrines of Koch and his followers, feeding upon half-cooked bacilli cannot be conducive to the most robust health.

SOCIETY PROCEEDINGS.

THE PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, December 28, 1885.

The President, S. Weir Mitchell, M.D., in the Chair.

Dr. Guy Hinsdale presented a communication on

THE METHODS OF SLAUGHTERING ANIMALS AT THE PHILADELPHIA ABATTOIR.

There has recently been put in my hands a series of written questions which relate to the methods of slaughtering animals in our Philadelphia Abattoir. The subject has been brought before the Society for the Prevention of Cruelty to Animals, and the officers of the Society desire to obtain from some of our Philadelphia physicians an expression of opinion as to the proper method of killing cattle with the minimum of pain.

As the members of this Society are doubtless aware, enormous numbers of cattle, sheep, and pigs are slaughtered at the abattoir in West Philadelphia. Into the main hall of the building, which is spacious, having a high roof, with good light and ventilation, the cattle are led in large numbers. They are apportioned to

about fifteen different pens or iron cages arranged in a straight line, each capable of receiving seven or eight bullocks. The iron bars of which the cages are made are separated about fifteen inches from each other, affording a comparatively unobstructed view of the remainder of the room. The gate of exit from a pen is opposite the gate of entrance; above it is the windlass for hoisting. The animal is, in most instances, struck down while standing among his fellows, by a butcher who stands on a plank above him armed with a heavy, long-handled sledge-hammer. He is then hoisted by the windlass through the open door, is disembowelled and dressed for the market within six feet of the animals remaining in the cage, When the carcass is ready for market one of the butchers climbs above the cage, and with the hammer strikes down two more animals; they are dragged out, and so on until all the animals are disposed of.

The Jewish butchers for ages have killed by bleeding. They never use a hammer, but after hoisting the animal by a hind leg, the throat is always cut by a rabbi or "shockem," armed with a keen sabre. This rabbi is detailed for duty at the abattoir.

Underneath the main hall is a cellar in which sheep and pigs are slaughtered by the knife. It is a dark, unclean, repulsive place. Large quantities of accumulated gore are seen in the places where the animals are usually killed. The surface drainage is very bad; the upper floor, though deluged with blood, is attractive in comparison.

The questions to which answers are desired by the Society for the Prevention of Cruelty to Animals are these:

1. Does the Israelitish method produce a total loss of sensation?

2. Does a total loss of sensation arise from a blow struck upon the head of the animal with sufficient force to knock him down?

3. What is the most humane way of slaughtering cattle, which would produce instantaneous death?

4. Do you think a bullock is so sensitive as to suffer terror or agony in witnessing the deathblows and sufferings of his companions?

With a view to satisfy myself on these points, I made three visits to the Abattoir. I had no especial interest in the subject before, and supposed that the methods were not open to criticism.

As for the first question, I think it safe to say that the Israelitish method is instantaneous when once the steel strikes the neck. The blood gushes out, the brain is instantly deprived of blood, and consciousness is lost without appreciable loss of time. The young rabbi deserves credit for the skill with which he performs this operation. To suspend animals with heels up and head down is, at first sight, somewhat harsh, but, on the other hand, they are accustomed to a low position of the head, and the new position is only ninety degrees removed from the normal.

Regarding the second question, it appeared to me that consciousness did not always cease when a blow was struck upon the head of an animal with sufficient force to knock him down.

The first two animals that I saw killed were struck on the head, in the middle line a little anterior to the line of the insertion of the horns. They instantly dropped; a few convulsive movements, sometimes unilateral, sometimes general, occurred, and they were removed from the cage. The next three animals were struck by a different man. Two animals were struck eight times apiece, and the others nine times before the butchers saw fit to proceed to dress the beef. Although the earlier blows were ineffectual, the later ones were delivered when the animals had lost sensation, and when the convulsive movements appeared too violent. In other instances one, two, three, or four blows were required. Animals were partially struck down, and did raise their heads, and look about, unquestionably conscious of pain. The ox is not by any means the only animal that may preserve consciousness after being struck down by a blow upon the head. We ourselves may know this from personal experience. However, one blow well applied was sufficient perhaps, in the majority of instances, instantly to destroy sensation.

Two other cattle which I saw killed at my third visit were attacked by a third man. The first received three blows upon the head, but still the animal walked about, and it became so difficult to induce him to stay still in proper position (the unreasonable creature!) that the butcher resolved to devote his attention to another animal, upon which, also, he delivered three heavy but ineffectual blows. I noticed by this time that the first animal was bleeding from the nose, and that both were able to walk about. This heavy hammer would sometimes bound from the skull as you might expect a wooden mallet to do. The animals gave no cry, and made no violent demonstration, as one might expect; they received these murderous blows as a prize-fighter might receive his, without evincing pain. They, however, became uneasy, endeavored to avoid the man crouching above them, and, without much trouble, were finally dispatched.

As to whether a bullock is so sensitive as to suffer terror or agony, in witnessing the deathblows and sufferings of his companions, interesting metaphysical questions are involved. Butchers in the abattoir do not seem to think that the animals are conscious of their surroundings. They say they occasionally milk a cow in a cage near which animals are being slaughtered. It is quite evident that, as a rule, bullocks make no attempts, or the most ineffectual attempts, to avoid the fate of their companions. In one instance which came under my observation, the last of a series of bullocks became frightened; he dodged the blows, put his head through the bars, and held it low, out of the reach of the butcher standing on the top of the cage. Men with sticks poked him about, while inaccurate blows fell upon his head, until, after a disgusting struggle, he was dispatched. This animal seemed to me to act at the start as though he appreciated danger from witnessing the death of his companions. Butchers say that Texan steers give more trouble than others, and are more liable to grow wild at the sight and smell of blood. It cannot be that their mental powers are radically different from those of other varieties of oxen.

It is not necessary to repeat before this Society anecdotes or proofs to show that a steer may become frantic at the sight and smell of blood. Carnivorous animals are not so susceptible. A dog may even eat another dog, as one of our proverbs says, and yet some dogs

are capable of sympathy, and exemplify it by appropriate behavior. Not only the elephant, but even so small a creature as the ant, manifests sympathy.[1] The sense and the understanding are not the prerogatives of man exclusively. These lower animals have attention, memory, association. They exhibit generosity, gratitude, courage, caution, patience, industry, anger, and grief.

Doubtless the ox or the sheep or the pig cannot claim the possession of all these qualities. But their mental system is much less perfectly understood than ours. "The popular tendency has been to underrate the acquired knowledge of animals, if not to ignore it altogether. At present we are not in a condition to dogmatize, owing to the want of proper observations on the whole department of brute intelligence."[2] As Lauder Lindsay puts it, "the very terms animality and humanity are, on the one hand, unnecessary distinctions; while, on the other, they are generally wrongly applied, for there is more animality in man and humanity in animals than our self-conceit will permit us willingly to recognize. We cannot correctly speak of the animal in contradistinction to the human mind, inasmuch as mind is essentially the same in other animals as in man, differing simply in the degree of its development and the mode of its expression."[3]

But what can be done to remove the objectionable features of this necessary work of slaughter?

1. The work of killing these animals should be given only to a man of experience and power.

2. It is not necessary, and it should not be permitted, that animals should witness the death of their fellows. They may wait their turn together, but finally should be led to an apartment alone, where a single successful death-blow may be given.

3. Means should be provided for making this blow unerring. A crushing blow on the brain-case is, undoubtedly, a painless death, and, by a mechanical contrivance, this might be made unfailing. Fixation of the head would be necessary, and perhaps could be accomplished by means of the horns. An experienced executioner, with an adequate instrument, either in his own hands or under his control, as a trip hammer is under the control of a forger, could then dispatch these poor brutes with the minimum of pain.

4. The number of men who perform this work should be small; and boys, women, and the public generally, should not be permitted to witness these brutalizing scenes.

5. The Jewish method, when rapidly performed, is, on the whole, not a cruel method.

6. The city should take immediate steps to supervise this abattoir; it should have an official inspector of meat, and adopt some effectual, scientific method for the detection and condemnation of diseased meat.

If this Society will endorse these statements, I believe that a better state of things can be secured. If proper evidence can be adduced, the Society for the Prevention of Cruelty to Animals will take hold of the matter and insist on reform in this important public institution.

DR. CHARLES K. MILLS moved that a committee be appointed to visit the abattoir, and report to the Society on the questions proposed by the Society for the Prevention of Cruelty to Animals.

The committee appointed consisted of Drs. H. C. Wood, H. A. Hare, F. X. Dercum, A. P. Brubaker, and Guy Hinsdale.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, February 3, 1886.

THE PRESIDENT, S. WEIR MITCHELL, M.D., IN THE CHAIR.

DR. HORATIO C. WOOD, on behalf of a Committee of the Philadelphia Neurological Society, made the following statement concerning the

PAINLESS SLAUGHTERING OF ANIMALS.

Some weeks ago, the attention of the Neurological Society of Philadelphia was called to the subject of the Philadelphia Abattoir, and the mode there employed of slaughtering cattle and sheep, by a paper by Dr. Guy Hinsdale. The subject was referred to a Committee, of which I had the honor to be the Chairman, for investigation, and, upon the making of our report, the Society directed me, as Chairman of the Committee, to bring the matter before the College of Physicians of Philadelphia, as the highest representative body of the profession in this city.

As is well known, there are yearly killed in the abattoir in West Philadelphia, owned by the Pennsylvania Railroad, many thousands of cattle, sheep, and hogs. The method of slaughtering the sheep and hogs is simply to cut their throats, and to allow them to bleed to death. If this be done skilfully with a single sweep of the knife, the death is rapid, but far from instantaneous, and consciousness is preserved until the blood is nearly exhausted from the body, the supply of the vital fluid through the vertebral arteries being sufficient to maintain temporarily a certain amount of brain function. In the case of sheep, pithing is a very simple operation, and any butcher, after a little practice, could do it with rapidity and ease. The amount of expended time which it would add to the present method is exceedingly small, and we can see no reason, except the callousness of custom, for objecting to its introduction. In the small slaughter houses of the olden time, a rope was thrown around the horns of the cattle, and the animal was violently dragged down to a ring in the floor, and then dispatched with a blow in the forehead. I understand that in the Paris abattoirs this method is modified so far that the bullock is driven into a narrow gangway or pen, a rope thrown round the horns and rapidly hoisted so as to raise the forefeet of the creature from the floor, when the fatal blow is given. In some of the great abattoirs of the West the animal is shot, and, of course, if the bullet be accurately directed, the victim dies instantaneously. In other places pithing is practised, and, if skilfully performed, produces immediate death.

The objection to shooting is the danger of the bullet either simply wounding the animal or occasionally, when discharged through carelessness or accident, passing wide of its mark. It is said that serious accidents have thus occurred in the Chicago abattoirs. Pithing is un-

doubtedly the best method of killing, provided the requisite skill is present, but its proper performance requires a much greater degree of skill than would probably be commanded in our city abattoirs. If the blow upon the forehead be given with a sufficiently heavy instrument, which is provided with a truncated point one and a half inches in diameter, and be well directed, it undoubtedly produces an effect which is as immediate and almost as thorough as that of pithing. I believe that under these circumstances the medulla itself will be found to be crushed or destroyed by the enormous hemorrhage. The idea of the plan which is adopted at the Philadelphia Abattoir appears to be as good as any that is practical, but the method of the carrying out of this plan is exceedingly bad. The main hall of the abattoir is spacious, well lighted and ventilated, and the centre is occupied with fifteen pens or iron cages, placed in a straight line on each side of an avenue. Each of these cages is capable of holding from seven to eight bullocks, and the view of the whole floor is practically unobstructed by the slight iron bars which separate the cages. Over the top of these cages are placed planks. The plan is for the bullocks to be driven into the pens, often until the latter are completely filled. The person who does the killing stands upon the planks above the pen, watches his opportunity, and strikes down one after another of the cattle beneath him. The hindlegs of the theoretically unconscious victims are then attached to a chain, and by means of a windlass the body is dragged out of the pen and suspended with its head downward. After this the throat is cut and the blood caught in buckets or tubs.

The first question which naturally arises is as to the amount of psychical suffering that is produced in the cattle by the sight of death or the smell of blood. After a good deal of observation the Committee of the Neurological Society came to the unanimous conclusion that the cattle had an imperfect consciousness of what was going on; most of them seemed entirely cowed and passive, whilst others were exceedingly restless and apparently very anxious. The Committee did not believe that the suffering would compare with that which would exist in human beings under similar circumstances, but it seemed to be quite definite and distinct.

As no provision is made for the animals being in the proper position for striking, the butcher who uses the hammer, selects his opportunity as best he may. Moreover, the weapon is used by a number of individuals, the result being that in a very large proportion, and, perhaps, in the majority of cases, a single blow is not sufficient. When first struck the animal falls to his knees, or, as in many cases, scarcely flinches, only striving with more or less eagerness to get away from a danger the existence of which he recognizes, but the direction of which he does not perceive; the beast is then driven about as best may be until an opportunity is afforded for a second blow; thus the process of torture is repeated until finally the animal falls. It is also the custom at the Abattoir to strike down three or four bullocks at once; so that some minutes must elapse before the cutting of the throats of some of them. Under these circumstances the unfortunate creature very frequently recovers partial consciousness before his turn comes, and not rarely regains sufficient self-possession to get upon his feet, when the process of striking-down has to be repeated.

Observation made by various members of the Committee, at different private slaughter houses in Philadelphia, shows that there is still greater carelessness and recklessness of animal suffering than in the public abattoir.

It is not necessary to enlarge at all upon the condition of affairs at the Philadelphia Abattoir. Fortunately the remedy is a very easy one, and it can hardly be that the officials of such a great corporation as the Pennsylvania Railroad will fail to apply a remedy when the evil has been brought to their attention. The arrangement of the pens should be remodelled, so that the bullock to be killed shall be isolated in a close, narrow pen, but especially should the striking be performed by one man, whose sole duty it should be to deliver the fatal blows. With the skill that would come with constant repetition, it is probable that it would not be necessary to raise up the head of the bullock at all, but if this be deemed advisable, over the horns of the animal, driven into the narrow pen, a rope could be readily thrown, and in an instant the feet raised from the ground.

Before taking leave of this matter, it seems right to call the attention of the College of Physicians to the very great need there is of some inspection of meat at the Philadelphia Abattoir. Of the dozen or fifteen cattle which I personally saw killed, the internal organs of one were simply studded with tubercular nodules, so that the beast must have been in the last stages of general tuberculosis. The meat was dressed and prepared as that of the others for sale. It is probable that this diseased meat especially finds its way into those forms of sausages which are largely eaten by a portion of our population in a partially cooked condition. It seems to be but right that protection should be afforded to the community against the use of diseased meat, and that, therefore, there should be an inspector having supervision over both the public and private slaughtering places of the city.

In conclusion, I trust that the subject of this communication will be referred to a committee with power to bring the matter, through the public press, to the attention of the citizens of Philadelphia.

Upon motion, the Chair was authorized to appoint such a committee, to consist of three Fellows, with power.

The President appointed Drs. H. C. Wood, H. C. Chapman, and E. T. Reichert as the committee.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, January 20, 1886.

THE PRESIDENT, CHARLES MCBURNEY, M.D., IN THE CHAIR.

DR. R. F. WEIR read a paper entitled

RESECTION OF LARGE INTESTINE FOR MALIGNANT GROWTH.

(See page 173.)

DR. BRIDDON remarked that notwithstanding Allingham's opinion that colotomy does not prolong life, he had seen life prolonged and made much more comfortable by colotomy in cancer of the rectum, where

the disease could not be entirely removed. He referred to a case of cylindrical epithelioma of the rectum in which, in the Presbyterian Hospital, he performed lumbocolotomy, and the result was that the general condition of the patient was very much improved, and she was rendered very much more comfortable with reference to the local condition.

Dr. H. B. Sands agreed with Dr. Briddon in his protest against the view ascribed to Allingham, that life is not prolonged by colotomy performed for the relief of cancer of the colon or rectum. He did not know how this conclusion, drawn by Allingham, was arrived at, but he thought it was within the experience of most surgeons present that they had often succeeded in prolonging life by this operation. He could recall several instances in which at the time lumbocolotomy was performed the patient was almost at death's door, and in which life was lengthened for a considerable period. He recalled the case of a patient in this city, in whom, at the time of the operation, there was complete obstruction of the bowel, accompanied with enormous distention of the abdomen, and Dr. Sands was sure that if mechanical relief had not been promptly afforded, he would not have survived more than three or four days. The patient had no bad symptoms after the operation, but recovered from it and lived more than a year afterward, being able, during the greater part of the time, to go about and attend to business. He could recall other similar cases. He had presented to the Society a man upon whom he had performed inguinal colotomy, and who, at the time of the operation, was suffering from complete intestinal obstruction. Dr. Sands believed it could be stated as an established fact that, in a certain number of instances, the operation will not only relieve the urgent symptoms, but also prolong life for a considerable period.

Dr. Briddon said that the most gratifying case in this respect which he had seen occurred about two or three years ago. It was one of acute intestinal obstruction due to malignant growth in the upper end of the rectum. He performed lumbocolotomy, which gave the man complete relief, and he lived for two or three years in a very comfortable condition. The obstruction had existed eight or ten days when he first saw the patient, and the abdomen was largely distended.

Dr. L. A. Stimson said with reference to a collateral point—namely, whether it is advantageous ever to attempt to remove a cancerous tumor of the intestine, that according to the record which Dr. Weir had given, the longest period of survival had been five years. For the encouragement of those who should have opportunity to perform the same operation, he would say that seven and a half years ago he had removed a cancer of the rectum, and the patient, a physician, is still in active practice and good health; there has been no return of the disease.

Dr. Sands said that if it proved to be the result of further experience, that the operation of extirpation of a cancerous intestine can be done in such a manner as to reunite the ends of the intestine, it would still be a matter of doubt whether such an operation, which involves a greater risk than simple enterotomy or colotomy, should be preferred to the latter, for he could imagine that it would be found in cancer of the intestine, as in cancer of the stomach, that surgeons would rarely succeed in making such a radical operation as to give much chance against recurrence of the disease.

Dr. F. Lange said that he had had the opportunity to perform the operation twice; in both cases for malignant growth. In the first case the growth was situated in the ascending colon near the right flexure. It seemed to be very movable, and the patient was in a comparatively good condition. He expected to find conditions favorable for an easy operation, but was very much deceived, for the tumor was intimately adherent to the duodenum. The operation was accompanied by a great deal of hemorrhage, and finally by lesion of the duodenum, which he was obliged to close with suture. He did not, in consequence, have much hope of the success of the operation. The woman died on the second day, of peritonitis.

In the second case he had not intended to perform an operation on the intestine. The case was one of particular interest. The woman, about thirty-two years of age and a widow, applied to him with reference to tumors which had developed comparatively rapidly, and which without much difficulty could be made out as belonging to the ovaries. Dr. Lange regarded the case as one of sarcoma of both ovaries, and did not encourage an operation. The patient had had for the past two years obstinate bloody diarrhœa which could not be controlled effectually by internal remedies, and immediately before the appearance of the diarrhœa she had suffered from an attack of acute dysentery. By her attending physicians the diarrhœa was regarded as being due to the preceding dysentery.

The patient urged that an operation be performed because there were special reasons why she should desire to live a little longer. Dr. Lange, therefore, performed the operation for removal of the tumors, which were taken away without difficulty, but he found to his great surprise that, attached to one of these ovarian growths, indirectly through the omentum, was a large circular tumor of the transverse colon, besides several nodules about the size of a hazelnut in the omentum, and there were also several enlarged mesenteric glands. As the patient was in a fairly good condition, and the operation thus far had not been prolonged, he determined to excise the intestine. The operation lasted about two hours and a half, and went on without much disturbance, and the patient came out from the operation in good condition. The first week was without trouble except that he was unable to check the diarrhœa. On the ninth day the patient died with acute symptoms of perforative peritonitis, which he thought was due to a suture giving way somewhere, in turn due to the incessant peristalsis of the intestine.

Dr. Lange presumed that in cases in which no complication exists the operation is very likely to be beneficial, and is one which will probably prolong life. He did not think that in all cases absolute rules could be stated. In scirrhus of the large intestine, which is movable and without complications, the operation is not more difficult or dangerous than exsection of the intestine for any other cause. The length of time for the operation under such circumstances, which can be performed without very much loss of blood, is not of great importance, if the operation is done with the necessary care and the patient's general condition altogether allows of such an undertaking.

Dr. Sands asked Dr. Lange whether he would not regard cancerous mesenteric glands as a contraindication to the performance of the operation.

Dr. Lange said that if he had known of the condition of the mesenteric glands before the operation he probably should not have undertaken it at all; but having operated and removed the tumors of the ovaries, he thought it was allowable to continue the operation in that case. As a rule, he should say involvement of the mesenteric glands is a contraindication to the operation.

Dr. Briddon asked Dr. Lange what material he used for sutures in the last case.

Dr. Lange thought he used fine silk in both cases.

Dr. Briddon asked Dr. Lange whether he would regard catgut as safe in these cases.

Dr. Lange said it would be safe if primary union took place; but, if such union did not occur, silk might give an additional amount of safety.

Dr. Weir replied that Mr. Allingham's opinion relative to the influence of colotomy upon cancer of the lower bowel did not apply to the relief of obstruction, but to its influence when used in the earlier stages of the disease.

KANSAS STATE MEDICAL SOCIETY.

Adjourned Meeting, held at Topeka, January 25 and 26, 1886.

(Specially reported for The Medical News.)

Monday, January 25.—First Day.

The President, H. O. Hannawalt, M.D., of Kansas City, called the meeting to order.

Dr. Cochrane, of Atchison, reported a draft of a bill from the Committee on

MEDICAL LEGISLATION,

which was received.

Dr. Stormont, of Topeka, opened the discussion by explaining the present law creating a Board of Health for the State, and the powers vested in it, stating that the Board as it is constituted is sufficient for all the purposes of an examining board, and to regulate the practice of medicine and public hygiene in the State, provided the law can be strengthened and made active by an Act which is now before the Legislature.

After free discussion, the proposed bill presented by the Committee was referred back to the Committee, to report again at the May meeting, and the Society expressed its approval of the supplemental Act now before the Legislature to give power to the State Board of Health.

Evening Session.

Dr. J. P. Knoche, of Kansas City, read a paper on

ECZEMA AND SYPHILIS,

the main points of which were: 1st. No such remedies should be given, as the iodides, bromides, etc., which have more or less action on the skin, in a case of syphilis where eczema exists, or a tendency exists. 2d. Where a surface is more or less constantly irritated, with eczema present, and there be syphilis in the system, the latter disease will in the great majority of cases give some evidence of its presence. 3d. Therefore it can be readily seen that it is necessary to recognize syphilitic eruptions that may be more or less intimately combined with the eczematous eruption. 4th. The local treatment of the eczema will avail little, unless the syphilis is treated in conjunction with it, or the specific infiltration is first removed by appropriate treatment. Two cases supporting this view were reported.

Dr. B. E. Fryer, of Kansas City, read a paper on

ENUCLEATION OF IRRITATING EYE, AFTER SYMPATHETIC OPHTHALMIA HAS BEGUN.

It was an exhaustive survey of the literature of the subject. The writer showed that authorities differ as to whether the operation is justifiable after sympathetic ophthalmia has begun, and called attention to the importance of the subject from a medico-legal standpoint. The pathology of the transmission of the inflammation from the irritating to the sound eye was not discussed at length. He favored the theory that it is conveyed along the lymph sheaths of the optic nerve. He then proceeded to quote several cases from his own experience, showing that enucleation is not only justifiable but necessary, even after sympathetic inflammation has begun.

Dr. Tiffany did not believe that there is such a thing as sympathetic neuro-retinitis, but that the inflammation is conveyed from the offending eye to the other by the ciliary nerves, and begins in the most vascular coat, which is the choroid; but he agreed with Dr. Fryer, that enucleation is justifiable after sympathetic ophthalmia has begun. He reported two cases, and presented specimens of ossification of choroid around the optic nerve in old stumps, where abscission of cornea had been done.

Dr. Murphy believed with Schweigger, that the inflammation is carried through the lymph channels which surround the optic nerve, and agreed with the author of the paper.

Dr. George Halley, of Kansas City, then read a paper on

HEMORRHOIDS.

In the treatment of the mild form of external piles, he advised that they be laid open with the knife and hot fomentations be applied.

For the milder cases of internal piles, he recommended the exhibition of a laxative, and quiet in bed, and that the tumors be injected with carbolic acid, ten per cent., in olive oil. In cases of long standing, he recommended division of the deep connective tissue and cicatricial bands with the knife in four or five places around the lumen of the rectum, care being taken not to divide the hemorrhoidal arteries. The operator should then divulse the rectum and smear with carbolized castor oil, quiet pain with suppositories of opium and belladonna, and build up the system with tonics.

Dr. Baldwin said that his experience with the use of carbolic acid injections was not satisfactory. They caused *extreme* pain and some alarming symptoms, such as retention of urine, etc.

Dr. Halley replied that if the point of the needle is inserted well inside the mucous membrane, into the tumor, but little pain will result, and no ulceration follow.

Tuesday, January 26.—Second Day.

Morning Session.

But few members were present, and all business of import having been transacted, a motion to adjourn until the third Tuesday in May, 1886, was carried.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 3, 1886.

The President, A. Jacobi, M.D., in the Chair.

SECTION OF ORTHOPÆDIC SURGERY.

Dr. Newton M. Shaffer reported that a Section of Orthopædic Surgery had been organized, and that at its first meeting Dr. Ketch read a paper on "Rotary Lateral Curvature of the Spine," which was discussed by Drs. L. A. Sayre, V. P. Gibney, C. F. Poore, L. H. Sayre, N. M. Shaffer, and others.

Dr. M. A. Starr read a paper on

THE INTRACEREBRAL TRACTS: THEIR PHYSIOLOGY AND ITS BEARING ON THE DIAGNOSIS OF LESIONS OF THE CENTRUM SEMIOVALE.

In it he described in detail the functions and relations of the three sets of fibres, the projection, the commissural, and the association fibres, so far as they are known at the present day, and stated that lesions of the centrum ovale may give rise to three sets of symptoms, referable to these three sets of fibres. In illustration of the subject, he gave an elaborate report of a case of Charcot's, of which he had had the opportunity of making a careful personal study, and exhibited specimens of brains which had been hardened for six months in alcohol and prepared by teasing in such a way as to show the various intracerebral tracts.

Dr. Crossman remarked that these tracts were not shown as satisfactorily in the specimens exhibited before the Academy to-night as they had previously been in Dr. Starr's office, where he had had an opportunity of seeing the fibres exposed by the teasing process, the demonstration at that time being absolutely perfect.

Dr. Aug. G. Caillé read a paper on

PERMANENT DRAINAGE IN ASCITES,

in which he first related the case of an elderly gentleman who came to him for treatment about four years ago, suffering from cirrhosis of the liver. This soon necessitated tapping, and in the course of the next seven months he was tapped no less than nine times. Before resorting to a tenth tapping, Dr. Caillé determined that he would make a fistula in the abdominal walls, and put in a permanent drainage tube. He, therefore, made an incision one inch in length in the linea alba below the umbilicus, and inserted an inch of drainage tube into the peritoneal sac, retaining it by means of a varnished safety-pin, and using antiseptic precautions in the dressings applied. In about a week an eczema of the abdomen and thighs developed, owing to the fact that the patient could not keep himself dry by means of the cloths with which he was supplied. The abdomen and thighs were then smeared with mutton tallow, and the eczema disappeared in six days.

The result of the permanent drainage was that the general œdema, and all the other distressing symptoms from which the patient had been suffering, disappeared. He was soon able to go about with ease, and for nine months was able to attend to his ordinary occupations, contented and comfortable. He finally died from heart failure. When the drainage tube was first put in, from two to three pints of fluid were excreted daily; but this gradually diminished, until it ceased entirely, and the ascites never reappeared. An autopsy was made, when it was found that there was cirrhosis of the liver, with cardiac hypertrophy. There was not the slightest evidence of peritonitis at the point where the tube had been inserted.

A second case was that of a male, forty-six years of age, who had been a confirmed whiskey-drinker, and who was suffering from cirrhosis of the liver, ascites, and general anasarca, with all the distressing symptoms usually attendant on such a condition. He also had purpura hemorrhagica, stomatitis, and vomiting, and the heart's action was irregular and miserable. He was tapped once, and then the fluid reaccumulating, Dr. Caillé made an opening and inserted a permanent drainage tube in the same manner as in the preceding case, protecting the parts with iodoform gauze and dry towels. When the patient was in bed or sitting in a chair, a rubber tube conveying the fluid to a vessel on the floor was often attached to the drainage tube. There was at once great improvement in the general condition; but about three weeks after the fistula was made the patient suffered from a severe attack of epistaxis, which necessitated the plugging of the posterior nares. The purpura, vomiting, stomatitis, and other troubles then disappeared, and he lived in comfort, without any return of the ascites, for a considerable period, finally dying of paralysis of the heart. In this case no autopsy was made.

Of course, he said, it was not claimed that this treatment is curative. Its object is simply the amelioration of the troublesome symptoms always associated with ascites. All the points involved in it are comprehended in a discussion of four questions: The first is, What are the symptoms most troublesome and dangerous in ascites? Ascites may occur alone, or associated with general anasarca; but in either case dyspnœa, flatulence, constipation, debility, renal trouble from the pressure of the fluid, and a host of other evils are liable to ensue.

The second question is, How is collateral circulation established in cirrhosis of the liver? The various channels through which this was accomplished were pointed out by Dr. Caillé.

The third question was, Will absence of intra-abdominal pressure promote collateral circulation, the functional activity of other organs, and the comfort of the patient, as well as tend to prolong life? This he answered in the affirmative.

The fourth question was, How is drainage best accomplished? It could not be denied, he said, that the large amount of fluid which was drawn from the system in the method which he was advocating constituted a considerable drain upon the vital forces, and he showed what a large amount of albumen would thus be abstracted in a given time; but, on the other hand, this was of comparatively little importance on account of the benefit derived from the better performance of the functions of other organs which resulted from the establishment of drainage.

He then went on to say that the *technique* of the proposed plan of procedure might be improved upon. For instance, a hard rubber or glass tube might be employed, and a flax bag, or antiseptic pad, to be worn on the abdomen below the fistula, might be provided. In all cases it is necessary that antiseptic precautions should be observed, though the danger from penetrating

the peritoneum is found to be much less when ascites is present than under other circumstances. A large experience, he said in conclusion, is needed to determine the indications for permanent drainage, and the cases in which it is applicable.

The President said that the procedure described by Dr. Caillé was an imitation of what is sometimes accomplished spontaneously by nature. Spontaneous rupture of the abdominal walls may take place in ascites, and it is not of very infrequent occurrence. It sometimes takes place in the linea alba, but most commonly at the umbilicus. The fistula made by nature, however, may be in a spot which is inconvenient and uncomfortable for the patient; but, when we make an artificial fistula, we can select the place which will be in every way the most satisfactory. Not long since, he had seen in the German Hospital a patient in whose case a spontaneous fistula had already been established when he came under observation. While he remained in the hospital he lost fifty pounds in weight, and he went out feeling comfortable and able to walk.

He then related another case, in which, he said, he had to resort to permanent drainage. This patient was a young woman, twenty-three years of age, in his service at Bellevue Hospital, who had a history of anæmia and chlorosis, and had attained the age of nineteen years before she began to menstruate. For six or seven months before admission menstruation had ceased, and some six months before the cessation she had noticed a circumscribed swelling in the right hypogastric region. This gradually increased in size until she came into the hospital, when it was found that the tumor was quite large. At that time, however, it was two-thirds in the left hypogastric region, and only one-third in the right. There was decided tympanites in the renal region and over the ascending colon. From the fluctuation recognized through the tumor he decided that it was a cyst, and probably an ovarian cyst originating in the right ovary. The uterus was normal.

An abdominal incision was made with a view of removing the tumor, when it was found that there was no cyst at all. The condition present was, in fact, ascites, with strong adhesions on both sides, and a glass tube was left in the abdominal opening for six weeks. In the meanwhile the fluid did not return, and the patient was discharged in an improved condition. Afterward, however, he learned that there had been a reaccumulation. In this instance the ascites was probably due to tubercular peritonitis, and the fatal termination was only a matter of time. Dr. Jacobi remarked that a number of years ago he had made precisely the same mistake in diagnosis, but it was one to which all are liable, since ascites, when thus circumscribed by adhesions, presents exactly the same characteristics as an ovarian cyst.

A third case which he related had come under observation after he had become acquainted with Dr. Caillé's procedure of forming an artificial fistula. The patient had cirrhosis of the liver, and suffered from icterus, purpura, epistaxis, dyspnœa, and loss of strength. He introduced a trocar through the abdominal walls, midway between the umbilicus and bladder, and through this inserted a sterilized tube into the peritoneal cavity. To this was attached a rubber tube to convey the fluid to a pail under the bed. This procedure was adopted as a palliative measure to give the patient, who was in a hopeless condition, as much comfort as possible, and the tube was kept in position until he died. At night it was usually plugged up with wax. The quantity of fluid which flowed through it at first was extremely large, but gradually became smaller and smaller. The general condition of the patient after the operation was favorable, but he finally died of exhaustion. At the autopsy there was not found the slightest evidence of local peritonitis. Dr. Jacobi said, in conclusion, that he was convinced that the plan proposed was a good one, and that he should repeat the operation whenever suitable cases presented themselves to him.

Dr. Lindley inquired whether any medicinal treatment for the relief of the condition was used in Dr. Caillé's cases, in addition to the establishment of permanent drainage?

Dr. Meyer stated that he had had under his charge a case of cellulitis ending in a large accumulation of pus, in which a fistula was spontaneously formed below the umbilicus. In this instance he made a counter-opening from the peritoneal cavity into the vagina, and through this the pus had been discharging for the last two years. The quantity has, however, been gradually diminishing, and the cellulitis was also decreasing. In ascites also, occurring in females, it had occurred to him, therefore, that it might be advisable to make an opening into the vagina.

Dr. Meyer, in reply to a question from the President whether in the case mentioned he was sure that the pus was in the abdominal cavity, said that he was positive of this, and that the patient had previously had peritonitis.

Dr. Caillé having stated that that in his cases great care was used in the selection of food, but that no medicine had been used except Horsford's acid phosphate, Dr. Lindley said that among the Dutch in South Africa he had found that honey was held in very high repute in cases of abdominal dropsy. He then related a case of his own there, in which, after tapping, the fluid rapidly reaccumulated. He was then persuaded by some of the old women to try the effect of honey, when, to his suprise, the man, although he had every symptom of cirrhosis of the liver, began to improve, and in time was apparently entirely cured. He would not pretend to give any explanation of this; but the great confidence in the efficacy of honey which was universal in that district, seemed worthy of notice.

Dr. B. F. Sherman, of Ogdensburgh, suggested that the peculiar virtue of the South African honey might, perhaps, be derived from the flowers from which the bees gathered it.

The President then made some remarks on the medicinal treatment of the affection in question. He was confident, he said, that he had seen cases of cirrhosis of the liver recover perfectly; but it was to be remembered that an interstitial hepatitis is not necessarily a universal hepatitis, just as interstitial nephritis, myelitis, and encephalitis might be partial, instead of involving the whole extent of the organ affected. In a number of cases which had come under his observation, in which the diagnosis of cirrhosis had been made by himself and others, the ascites had disappeared, and never returned; the liver getting smaller, without a corresponding enlargement of the spleen, and the patient becoming practically well.

The treatment was, to his mind, very simple. When we meet such cases of interstitial inflammation in practice, and can make out a history of syphilitic trouble, we always congratulate ourselves and the patient on this account, because of the more favorable prognosis which it enables us to make; there being a fair chance of recovery as a result of an appropriate course of treatment with iodide of potassium and bichloride of mercury. He then remarked that as a student he had been taught that it was a cruel thing to give mercury; that it was antiplastic, and that if with it you succeeded in curing the disease present in any case, it was only to destroy the patient with the remedy employed. Except in syphilitic cases, therefore, for a number of years he used no mercury whatever in his practice. During the last ten or fifteen years, however, he had been endeavoring to make up for this mistake in regard to this really most useful agent. He had found by experience that in various forms of interstitial inflammation mercury is often very beneficial, and in this connection he related a case of tabes which he had had under observation for about twenty-five years. For a long time there was no improvement, although nitrate of silver and other agents had been faithfully tried; but since he had resorted to the use of mercury there had been marked progress, and the patient, although he had never had syphilis, was now practically well.

In interstitial hepatitis, nephritis, myelitis, and encephalitis, therefore, he would recommend the use of mercury; and it should be given in such a form and in such doses as could be taken for a long time. As a rule, the bichloride is the most suitable preparation, and it might be given, largely diluted, in solution, or preferably in pills, the ordinary amount called for being about one-tenth of a grain three times a day. The patient should be instructed to use a chlorate of potash wash, and to watch his gums carefully. The cyanide of mercury has been recommended by some; but he has had very little experience with it.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, January 22, 1886.

THE PRESIDENT, T. G. RODDICK, M.D., IN THE CHAIR.

DR. WM. GARDNER exhibited the following pathological specimens:

(1) FIBROID POLYPUS OF THE UTERUS.

This was about the size of an orange, and was removed from a woman aged 48, the growth being in the vagina, and was attached along the whole length of the posterior wall of the uterus. The patient was much blanched by hemorrhage, which had lasted almost constantly for five years. She made a good recovery.

(2) DISEASED OVARIES.

These were two in number, and were slightly enlarged and cystic. They were the second ovaries from two cases of ovariotomy. The tumor in one case was an unilocular ovarian cyst, and in the other an ordinary multilocular cystoma. In each case the uterus was enlarged and retroverted, and menorrhagia had in both been a prominent symptom. Dr. Gardner remarked that in such cases where the second ovary is diseased, the question arises as to what should be the proper treatment when part of the ovary seems healthy. Schröder has recently published reports of a number of cases in which, instead of complete removal, he had excised the diseased tissue by a wedge-shaped incision, and brought together the cut surfaces by sutures. The object in such cases is to permit, if possible, of subsequent conception. Dr. Gardner was not aware, however, of conception having occurred under such circumstances. He thought that, after ovariotomy, the second ovary had often been unnecessarily removed, as slight enlargement and a cystic condition do not necessarily imply that an ovarian tumor will be developed therefrom. The responsibility on the part of the surgeon in dealing with such conditions assumed a new aspect in the light of Schröder's experience.

CEREBELLAR DISEASE.

DR. GEORGE WILKINS read a paper on the above subject, and reported the following cases:

Case I. Cerebellar Hemorrhage.—On the 2d of November, 1882, I was called to see a young lady, æt. 19, who, I was told, had had a fainting fit which she had not come out of. She had arisen at her usual hour, and expressed herself as being well. She went down to breakfast, but soon complained of a most intense pain in the head, accompanied by vomiting. The vomiting relieved her somewhat. Her mother left her lying on a sofa and returned in a few minutes to find her, as she supposed, in a fainting fit. Dr. Wilkins was sent for, and, on his arrival within a short time, found that the girl was dead.

A post-mortem examination could not be obtained till two weeks after death, and was performed by Dr. Wm. Osler. The brain was the only portion of the body allowed to be examined. On removing the brain, nothing abnormal was seen on the upper surface of the hemispheres, but the under and lateral surfaces of the right temporal lobe were covered with an extensive but thin clot, as were also the pons and medulla. The right lobe of the cerebellum was considerably larger than the left, and, on cutting into it, a large clot the size of a plum was observed close to the central lobe. On examining more closely, a pinhole aperture was seen on the superior surface of this lobe, and the internal clot was through this opening continuous with the clot covering the temporal lobe. Death, of course, was caused by pressure on the medulla from the blood which escaped from a ruptured bloodvessel in the cerebellum.

Case II. Cerebellar Hemorrhage (?).—A year ago last December I was called to see a young lady, æt. 16, who had been complaining of headache, which her mother thought to be biliousness. Two days before, she had awakened in the night, complaining of intense pain in the back of her head, accompanied by vomiting. Both lasted for five hours, and then gradually ceased. Next day she remained in bed, and suffered but little. During that evening the pain became again intense, and the vomiting returned. On the following morning she was seen by Dr. Wilkins, and then complained of constant and acute pain in the left occipital region. Temperature was normal, and pulse 72. At the time the pain was thought to be possibly neuralgia, and hop poultices were ordered to the back of the head, and

bromide of potassium internally. Next morning at eight o'clock she was seen again, and was comparatively easy; but her parents said she had been in agony all night. Her temperature and pulse were still normal. Dr. Wilkins was puzzled to account for the symptoms, and suspected tubercular disease of the brain. On visiting her at 2.30 P. M. the same day, he found she had died about five minutes before his arrival. For some hours before her death she had complained of general numbness, and her intellect was not clear. The pain ceased some two hours before death. No autopsy was allowed, but, from the symptoms and sudden termination, the reader of the paper considered himself justified in regarding it as a case of cerebellar disease.

Case III. Cerebellar Abscess.—John F., æt. 17, was admitted into the service of Dr. Wilkins, at the General Hospital, June 10, 1885, suffering from malaise, headache, vomiting, dizziness, and general weakness. Patient was a strong, healthy boy previous to present illness, which commenced some two weeks before admission. About this time he had a fall, striking shoulder and head, which caused a severe attack of vomiting, and confined him to bed for several days. On going back to work he got wet, and complained of pains in head, back, and body generally, and the vomiting and dizziness returned. These symptoms gradually increased in severity up to date of admission. On admission it was noted that he was stupid and lethargic; his pupils were dilated, tongue coated, and there was loss of appetite; had also insomnia and constant vomiting. Temperature 100°, pulse 70. Case was regarded as a mild attack of typhoid. The headache still continuing, an ice cap was ordered for his head, and bromide of potassium given in drachm doses at bedtime. On June 13 he became very stupid and restless, insisted on getting out of bed, could walk, but was very unsteady and weak, a swaggering gait. On June 16, four days after admission, on making his morning round, the House Physician, Dr. Gustin, found the patient cyanotic and almost asphyxiated, and he died soon after. The post-mortem showed pus in the arachnoid space, between the medulla and right side of cerebellum, and in the right lobe of cerebellum was found an abscess the size of a large filbert.

Dr. Wilkins, in speaking of the second case, said he thought he was quite justified in placing it under the head of cerebellar disease, because of the sudden termination of life without convulsive symptoms, and the continuance of consciousness. He thought these symptoms could only be explained by the occurrence of a hemorrhage from the cerebellum finding its way to the floor of the fourth ventricle and there compressing the motor sensory tract. The abscess in the third case he considered to be due to the fall which the patient had two weeks before admission to the hospital, as he was quite well before that time.

Dr. Wilkins alluded to the fact that the brain rests on a water cushion (first pointed out by Hilborn), which breaks the force of blows, but in some parts the brain is in contact with its bony walls, as, for instance, the brain rests on the orbital plates of frontal bones anteriorly, and the occipital bone posteriorly. Hence the frontal lobes and cerebellum, in blows upon the skull, are more liable to injury.

In this connection Dr. Wilkins showed the Society a specimen of hemorrhage into the white substance of the right frontal lobe. The case was that of a man who, while intoxicated, fell down stairs. He lived ten days after the accident and complained but little of pain, showing the insensitiveness of the brain itself. The intense pain of the first case was readily explained by the pressure caused by a blood-clot between the membranes of the brain, these latter possessing sensitive fibres.

In Cases I. and II. the persistent vomiting with constant and severe pain in the head and intense restlessness, Dr. Wilkins held, was significant of cerebellar disease.

DR. GEORGE ROSS said that many of the cerebral cases were at first thought to be bilious attacks, but the severe character of the pain should exclude this supposition, and if vomiting were present the case could not be looked upon as neuralgic. He thought it a pity that an ophthalmoscopic examination had not been obtained. In Dr. Wilkins's third case, which was long-continued, he had no doubt an ophthalmoscopic examination would have shown an optic neuritis.

DR. HENRY HOWARD said that the symptoms recorded by Dr. Wilkins in his second case were not necessarily those of cerebellar disease, as the same symptoms might be produced by pressure on the pons medulla from hemorrhage into the fourth ventricle.

DR. GODFREY thought that many cases of cerebral hemorrhage were benefited by free bleeding, and he was amazed that bloodletting as a method of treatment had of late years been so entirely abandoned.

DR. ARMSTRONG related the case of a man aged forty-five, who had a very severe headache which lasted a few days and then disappeared; it returned again and was accompanied by vomiting. The man soon died, and a post-mortem revealed a large clot covering the left side of the base of the brain. He asked whether there was any specific history in any of the cases reported.

DR. STEWART asked Dr. Wilkins what reasons he had for thinking his case was one of cerebellar hemorrhage.

DR. KENNEDY related a case of sudden death in a woman from supposed cerebral hemorrhage, which was at first treated as a case of hysteria. There was no vomiting in this case, and but little pain.

DR. MIGNAULT asked why bloodvessels should rupture in the brains of apparently healthy young women. It seemed strange that rupture should take place without previous disease of the vessels.

DR. WILKINS, in reply, stated that there was no evidence of specific disease in any of his cases. He looked upon the second case as one of hemorrhage because of its suddenness and the fact that the temperature was normal. Had the case been one of abscess or tubercular disease, the course would have been less rapid and there would have been higher temperature.

NEWS ITEMS.

YELLOW FEVER COMMISSION.—The House Committee on Commerce has agreed to report favorably a bill for the appointment of a commission of three to visit Mexico, the Central American States, and Brazil, for the purpose of investigating the methods pursued in those coun-

tries for the protection of the people against yellow fever. The bill provides that two members of the commission shall be appointed from among persons now in government employ, and the third from civil life.

PENNSYLVANIA LEAGUE FOR THE PROTECTION OF SCIENTIFIC RESEARCH.—There was recently formed in Philadelphia an association known as the Pennsylvania League for the Protection of Scientific Research. The objects of the League are in general terms stated in its name, but we understand that the intention is to resist all attempts to obtain any legislation in regard to vivisection beyond that which now exists upon the statute books of the Commonwealth. It is held by the society that the general act for the punishment of cruelty to animals is all sufficient for the prevention of any abuse of scientific methods.

There are two classes of members, active and honorary. The annual dues for active members is fixed at $2; and we understand that any member of the regular profession, in good standing, will be accepted as an active member, no formality being necessary, except to send an application to one of the officers. The officers are a president, secretary, and treasurer, and an executive committee of three. Dr. H. C. Wood was elected President, and Dr. Hobart A. Hare, Secretary and Treasurer. The executive committee has not yet been nominated.

OBITUARY RECORD.—At his residence in New York, on the morning of February 7th, after a brief illness, ALFRED C. POST, M.D., Professor Emeritus of Clinical Surgery and President of the Medical Faculty of the University of the City of New York.

Dr. Post was born in New York on January 13, 1806. He entered Columbia College, and was graduated in the Arts in 1822. A year afterward he entered the office of his uncle, Dr. Wright Post, an eminent surgeon, and began attending the lectures at the College of Physicians and Surgeons. After receiving his degree, in 1827, he went to Europe, and attended lectures in England, Ireland, and Scotland. Then he went to Germany and France to continue his studies, and spent a number of months in the large hospitals at Paris and Berlin. He came back to America after an absence of two years.

A few days after his return, in 1829, he was appointed House Surgeon of the New York Hospital, and within a year became assistant to Dr. Alexander H. Stevens, the Professor of Surgery in the College of Physicians and Surgeons. He was elected Surgeon to the Eye and Ear Infirmary in 1830. In 1851 he was appointed to the Professorship of Surgery in the Medical Department of the University of the City of New York, a position which he held up to 1875, when he was made Emeritus Professor.

He was a member of the County Medical Society, the Academy of Medicine, the Pathological Society, and the Surgical Society; Consulting Surgeon of St. Luke's and the Presbyterian Hospitals, President of the New York Missionary Society, and Director of the Union Theological Seminary. He leaves three sons and four daughters.

THE DEATH OF DR. JULES GUÉRIN, the dean of medical journalism in France, and the founder of the *Gazette Médicale de Paris*, has just been announced. Born in 1801, he was graduated in medicine in 1827 after six years of study under Chaussien, Boyet, and Roux. In 1837 he was a successful competitor for the *grand prix* in surgery, and it is stated that the thesis then presented on the deformities of the osseous system would, with the additions he has since made, fill some sixteen folio volumes of text, besides one hundred tables and four hundred plates. It is hoped that some means will be found for insuring the publication of this most valuable monument of industry.

NOTES AND QUERIES.

A CORRECTION.

To the Editor of THE MEDICAL NEWS.

SIR: Permit me to say, in reply to Dr. Massey's criticism, in THE MEDICAL NEWS, of my note, that in allowing him 100 ohms for the resistance of the metal circuit, I referred to the external resistance less that of the cotton. The "metal circuit" comprises wire and *milliampèremeter*. Milliampèremeters are of *high* resistance; why this is so, will be found explained in *Elementary Lessons in Electricity*, by Silvanus Thompson, pages 161 and 314. Mr. Barrett, whose milliampèremeter I am informed Dr. Massey uses, writes me that its resistance is 170 ohms; my allowance is therefore 70 ohms *less* than it should be. Waite and Bartlett inform me that their milliampèremeter has a resistance of 175 ohms.

I am, very truly yours,

GRANVILLE FAUGHT.

115 NORTH FIFTEENTH ST.,

ORIGINAL LECTURES.

ON NEW PULMONARY MEDICAMENTS.[1]

A Clinical Lecture, delivered in Cochin Hospital.

BY PROFESSOR DUJARDIN-BEAUMETZ,
OF PARIS, FRANCE.

GENTLEMEN: I shall occupy this lecture with a brief consideration of three new pulmonary medicaments: *Euphorbia pilulifera*, *terpine*, and *terpinol*.

The best antiasthmatic medication is surely that of which the basis is iodide of potassium, and when Green in 1860, Aubree in 1864, Trousseau in 1869, and, more emphatically still, Germain Sée in 1878, made known the happy effects of this remedy in the treatment of asthma, they rendered to medicine a signal service; you can, in fact, see any day in our wards cases illustrating the truth of this affirmation.

You know very well how we formulate this treatment; we begin by moderate doses of seven or eight grains and gradually increase them to thirty, forty, and even sixty grains a day. I am in the habit of ordering the iodide of potassium to be taken in milk, directing my patients at the same time to drink a great deal of milk during the day. We must, in fact, to prevent accumulation of the medicament, favor its elimination by the urine. While continuing the usage of milk, I think that the best vehicle for the administration of iodide of potassium is ale, which, in my opinion, disguises its taste better than anything else. We are in the habit, then, of ordering the patient to take at meal-time, in a tumblerful of bitter ale, a dessertspoonful or a tablespoonful of the following solution:

℞.—Iodidi potassii . . . . . ℥iij.
Aquæ . . . . . ℥vj.—M.

I sometimes add to the above tincture of lobelia, in the proportion of two or three fluidrachms to the entire quantity; if, however, the lobelia causes nausea, it must be omitted from the prescription.

Despite all your precautions and all your endeavors to make the iodide palatable and well tolerated, there will be persons who cannot support it, and who cannot take it in the smallest doses without suffering many of the symptoms of iodism. Therefore succedanea to iodide of potassium have been sought for, and among these I must make special mention of *Euphorbia pilulifera*. This plant has been especially studied in our hospital service by Dr. Marsset.[2] Euphorbia pilulifera belongs to the great family of Euphorbiaceæ, which has furnished to medicine very energetic purgatives, such as croton tiglium and caper spurge; it is an herbaceous annual plant, growing in Brazil and other tropical countries, and in Australia; the specimens which served for our clinical experiments came from Queensland, Australia.

The active principle is an acrid resin which is soluble in water and dilute alcohol. When the aqueous extract or the hydro-alcoholic extract is administered to animals, such as frogs or guinea-pigs, it is observed that in the case of frogs this extract is toxic in the dose of ten to fifteen centigrammes, which corresponds, nearly, to five grammes of the dried plant to one hundred grammes of the weight of the animal. In the guinea-pig the toxic dose is less; the animal succumbing to a dose of fifty or sixty centigrammes of the extract, equivalent to about one gramme of the dried plant per one hundred grammes of the animal's weight.

When we come to inquire into its physiological effects, we note that it acts chiefly on the respiratory apparatus, and that to a period of acceleration succeeds a period of retardation of the respiratory movements and beatings of the heart; hence, it is probable that this medicine acts directly on the respiratory and cardiac centres.

Dr. Mattheson, in 1884, was the first to call attention to the action of euphorbia pilulifera in the treatment of asthma, and Dr. Tison, of France, was the first to utilize this property in dyspnœas of asthmatic and even of cardiac origin.

From a pharmaceutical point of view you may make use of the following preparations: (1) The hydro-alcoholic extract of the plant, which may be given in the dose of ten centigrammes (one and two-thirds grains) a day; (2) or the decoction, which Dr. Tison directs to be prepared by steeping half on ounce of the dried plant in two quarts of water; the dose to be three or four wineglassfuls a day. (3) I am myself in the habit of using the tincture of euphorbia, of which I give ten drops three times a day. I recommend you to cause this preparation to be taken shortly before meal-time in a cup of some aromatic infusion, such as polygala or wall pellitory. You will thus avoid the local irritant action which characterizes almost all the extracts of this spurge. (4) There exists, lastly, a syrup made by Petit, which contains five centigrammes of the extract in each tablespoonful.

In patients suffering from dyspnœa, whether resulting from simple asthma, or from pulmonary emphysema, or even a cardiac affection, euphorbia has sometimes given us good results, but it will not do to give too large doses, and of the tincture, from five to ten drops, before each of the principal meals, are enough. Notwithstanding all these precautions, you will not be able to keep up this treatment more than a week without interruption, for the patients are apt to experience a burning sensation in the stomach, which results from the local irritant action of the medicament. It is, therefore, chiefly as a succedaneum of iodide of potassium, when the latter cannot be well borne, that you will resort to euphorbia pilulifera.

Terpine and terpinol fulfil indications absolutely different, and are applicable in catarrhs of the lungs.

[1] Translated, from advance sheets, by E. P. Hurd, M.D., of Newburyport, Mass.

[2] Marsset: On Euphorbia Pilulifera, Therapeutic Gazette, Feb. 1885, p. 92; Thèse de Paris, 1884.

In my *Clinical Therapeutics* I have insisted on the great advantages which may be derived from copaiba in the treatment of pulmonary catarrh, but this medication can have but limited application; for, to say nothing of the repugnance which many patients have toward copaiba, and its unfortunate association in the minds of most people with gonorrhœa (which increases the prejudice against it), there are certain unpleasant physiological effects often attendant on its use, such as eructations, diarrhœa, and divers cutaneous eruptions, which militate against the usefulness of this drug.

Therefore, while recognizing how happily copaiba modifies expectoration, it is only in hospital practice that I apply this excellent medicament to the treatment of pulmonary catarrh. I believe that I have found in terpinol a very fortunate substitute for copaiba, and one which offers all the advantages of the latter, without any of its disadvantages.

When turpentine is distilled in presence of an alkali, there is obtained a special hydrocarbon having for formula $C_{10}H_{16}$; this is *terebinthene*, which undergoes hydration, and thereupon furnishes a white, solid, crystalline body, which is the *bihydrate of terebinthene*, or *terpine*. This terpine, in presence of an acid, such as sulphuric or hydrochloric, is transformed into an oily body, to which has been given the name of *terpinol*.

Terpine was employed for the first time in therapeutics by Prof. Lepine, of Lyons, and, as a result of experiments on man and animals, he found that this body might be with advantage substituted for turpentine, and that it acted as expectorant and diuretic; his dose of terpine is twenty to sixty centigrammes (three to ten grains). We have reproduced in our service the trials of Prof. Lepine, and our pupil Dr. Guelpa has interested himself particularly in this undertaking. Terpine presents a real inconvenience in its slight solubility, requiring, as it does, 200 parts of cold water to dissolve one part of this substance; therefore, it is necessary to have recourse to alcohol in order to obtain active solutions; which is a drawback when one desires to prescribe it for diuretic purposes.

We have given terpine in much larger doses than M. Lepine; we have administered one, two, and even three grammes a day without obtaining any well-marked diuretic effect; so, in accordance with Tanret's suggestion, we have substituted terpinol for terpine.

Terpinol is an oily liquid body, which gives forth a very strong odor of tuberose (polianthes tuberosæ), and especially of gardenia (cape jasmine). Adrian has made for me capsules with terpinol, each containing ten centigrammes (one and two-thirds grains), and we give our patients six, eight, ten, and even twelve of these capsules a day. Terpinol may also be given in pill form, and here we give Tanret's formula, which can hardly be improved upon: Take of terpinol, benzoate of soda, of each, ten centigrammes (one and two-thirds grains), sugar, q. s. for one pill. These pills contain the same quantity of terpinol as the capsules.

We have made several experiments on animals, and have noted: 1. The rapid elimination by the respiratory passages of terpinol, which long imparts its special odor to the breath; 2. Its feeble elimination by the urine, which also gives forth the odor of terpinol, though much less markedly than the breath.

We then made trials of terpinol in two orders of complaints, pulmonary catarrh and affections of the urinary passages. As might have been foreseen, it was in pulmonary catarrh that we obtained the best results, since it is chiefly by the pulmonary surface that terpinol is eliminated. The sputa become more fluid, their bad odor disappears, and expectoration is facilitated. In affections of the urinary organs, the results have been almost nil. As a diuretic and modifier of the urine, it has shown itself very much inferior to turpentine.

So that if we were to attempt to classify these three substances, turpentine, terpine, and terpinol, according to their therapeutic effects, we should say that for the catarrhal affections of the bronchi, terpinol deserves the first place, and turpentine the last, while in the case of catarrh of the urinary organs, the order is exactly the reverse. This completes what I have to say at present on the subject of new pulmonary medications and antiseptic medication.

ORIGINAL ARTICLES.

PHYSIOLOGICAL STUDIES OF THE KNEE-JERK, AND OF THE REACTIONS OF MUSCLES UNDER MECHANICAL AND OTHER EXCITANTS.

BY S. WEIR MITCHELL, M.D.,
MEMBER OF THE NATIONAL ACADEMY OF SCIENCES,
AND
MORRIS J. LEWIS, M.D.,
ASSISTANT PHYSICIAN TO THE INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA.

(Concluded from page 173.)

Faradic electricity. A moderate current (short circuit, poles four to five inches apart), sufficient to move muscles, without pain, was used on the thigh, feet, arm, or hand, with the result of increasing k.-j. A current violent enough to give rise to pain and muscle-cramp sensations, or the abrupt use of a wire-brush on dry skin increased the k.-j. powerfully. The latter experiment—*i. e.*, the application of the wire-brush—produced almost as marked an effect on the k.-j. as anything that we tried, and left the skin so sensitive that a light touch at once increased k.-j.

Galvanism. This gave far more interesting results. Ten or twelve cells of an active zinc and copper battery caused slight but distinct burning sensations when placed on the skin three inches apart. Thus used anywhere on the leg struck, the opposite limb, the arms, hands, back, or flanks, they increased the k.-j., or, when they did not, the addition of five or six cells insured this result. In these short circuits the direction of the current seemed of no moment; but it was of importance to make and break the circuit to get the most marked result. This was effected by applying the two poles at once to the skin.

Galvanism to head, back, etc. The startling results obtained by the coincident use of knee-tap and currents through the head appear to open new paths of investigation. A great number of these experiments have been made by the authors, with the aid of Drs. J. M. Taylor, S. C. Wood, T. R. Neilson, W. J. Taylor, and G. Hinsdale. As they involved the passing of powerful currents through the brain,

every neurologist will understand the risks and the discomforts to the physicians who subjected themselves to these experiments. We may add, that persons are sometimes met with who feel very little vertigo or distress from powerful currents through the head, and who yet give good reactions as regards the influence these currents exert on the k.-j.

It will be, of course, needless to state all of our observations; of necessity, there were many failures, and the whole investigation should lead to laboratory study on animals, from which more accurate and more clearly explanatory results may be looked for. Their influence on the therapeutics of electricity seems also to be promising.

The subject being placed at rest on a lounge, with one leg on the crutch-rest, or held up in a loop, one pole of an open circuit of twelve cells is placed on each temple. An assistant has on the floor an apparatus enabling him to change the direction of the current, and to make or break circuit abruptly. A second assistant taps the tendon at intervals of three or four seconds. The assistant who controls the current watches his chance, and, without notice, makes and breaks circuit. Under these circumstances making circuit causes, of course, subjective sensation of light, some muscle movement of the temporals and occipito-frontalis, and more or less vertigo (fifteen cells or fewer), with notable increase of k.-j. This experiment always succeeds, but, in some subjects, a larger number of cells must be used. The effect wears out after a few repetitions. Breaking circuit causes little or no increase of k.-j.

The same experiments were made with the poles over the leg centres, or with one on the temple and one behind either ear, or with both behind the ears; but although the latter caused most vertigo, and all gave increase of k.-j., none gave as remarkable a result as when the two temples were within the circuit. This may perhaps be due to the thinness of the temporal bones or may await some more satisfactory physiological explanation.

Polar effects of galvanic current. To test this, the subject, as before, was placed on the lounge and the positive pole was held on the temple, while the negative was placed on some indifferent spot, on the clavicle or on the hand. With ten cells, but little sensation was produced at the positive pole, and on making and breaking the circuit no effect was produced on the k.-j. When a greater number of cells were used, the sensations of burning and pricking became much more marked under the positive pole, and the k.-j. was reinforced. On moving this pole about the temple certain regions were found which gave more scalp pain than others, and making the current at these points gave the most reinforcement to the k.-j.

A very different result was found to follow the placing of the negative pole on the temple. In this case a marked increase of k.-j. was seen, even with currents that gave no results with the poles reversed, and when thirty or thirty-five cells were used the effect was proportionally greater.

The sensations experienced were entirely different with the two poles; the first gave the most scalp pain, while the second gave an indescribable sensation within the head. These results were obtained whether the tendon on the same side or on the other was struck. Not so marked a result was obtained when the positive or negative pole was placed over the leg centres, as on the temple.

The effect of galvanism to the head is so decisive that it is difficult to explain it as being merely the result of a combination of influences, and yet it may be that it is so active because it affects at one and the same time, taste, sight, and general sensibility, and also gives rise to motion.

Galvanism and muscular effort combined. The same observations were made with the addition of violent and abrupt muscular effort. In this case as passivity is needless, the subject himself makes circuit either with the free foot or hand, while he strongly closes both hands. Of course, he watches the fall of the hammer, or, in case of constant excitations by frequent knee-taps, may neglect to do so. In either case coincidence of patellar blow, making circuit, and muscular effort gives the largest amount of increase of k.-j. in any way obtainable.

As to the next observation, it must be said that it is often difficult. It succeeds best with a fresh man in the morning, and has been made on the ignorant and unprepared as well as on ourselves. It succeeds to-day and fails to-morrow. In one instance it failed with four persons at nine P.M. of a warm, moist relaxing day, having succeeded before and since with at least two of them. As it demands the most powerful current a man can bear, it is needless to say that we hesitated to repeat it often. Indeed, in one or two cases, headache and vertigo, lasting an hour or two, followed it.

With the individual seated or supine (thirty to seventy cells) current through temples. Violent synchronous closure of both hands. Knee-tap. Very great increase.

Same conditions. A blow on the *tibia alone*, quite below the tendon, coincident with making current, caused distinct k.-j. Then the leg was steadied by a hand on the calf, to prevent swing, and the same phenomenon was seen. Next the muscles in front of the leg were tapped sharply, and a k.-j. obtained. These effects were absolute, and were verified over and over. They can be had only three or four times, and then not again for some time.

It seems clear that a combination of strong galvanization of the brain with violent voluntary action is capable of making the muscles as sensitive as they sometimes are in disease, and that under these circumstances we get response to such milder forms of stimulation as a tap on the tibia.

The most probable explanation of this remarkable phenomenon is that it is due to the imperceptible stretching of the quadriceps muscle by the blow on the tibia. In cases of spastic paralysis where it is obtainable with the greatest ease by the slightest percussion of the tibia without the aid of combined muscular movements elsewhere, or electricity through the head, if an assistant slowly extends the leg while the operator steadily taps the tibia, the k.-j. is not observable unless the blows are delivered with a considerable increase of force, because the forward

movement of the leg neutralizes the influence of the backward impetus given by the blow; a blow forward on the internal border of the shaft of the tibia does not produce the k.-j. This experiment could not be verified on a healthy subject, as this form of k.-j., the product of voluntary motion and galvanism, is slight and disappears so soon. The observation shows, however, how enormously the k.-j. is increased by the combined influences mentioned.

The "front tap contraction" described by Gowers, may also be explained in the same manner. To elicit this symptom the foot is pressed up until the calf muscles are tense, the leg being extended on the thigh with the calf resting on the operator's knee; a tap is now delivered upon the anterior group of muscles, or on the tibia, an imperceptible pull is thus made on the tendo Achillis as the result of the slight downward movement of the leg which is followed by an answering jerk of the calf muscles.

This phenomenon has heretofore only been observed in disease, but we have succeeded perfectly in producing it in health, by the conjoint use of galvanism through the head and violent voluntary movements of the arms, and also by the latter conjoined with the electric wire brush. We attempted to produce an ankle clonus in the same manner, but failed.

Galvanic currents to head with sensory stimulation to skin elsewhere. The use of head currents with pinching or freezing of the skin gave a larger addition to the k.-j. than did either alone.

Galvanism to spine. With subject at rest in a reclining chair, or lying on his side on a lounge, or seated, one pole was placed on the first cervical vertebra, and the other on the last lumbar; descending current thirty to seventy cells, caused moderate increase of coincident k.-j.

Ascending current gave great increase of k.-j. The best results were had with interruptions which were not very abrupt. As there are pain, flash, taste in the mouth, both here and in the case of the head muscle movements, it is difficult to be sure as to the mode in which the current acts; certainly neither direction of current lessens the jerk, and the phenomenon of increased k.-j. seems to have relation rather to the making than to the rupture of the galvanic circle. It were also as well to add that the effect of these long circuits demands for its full expression subjects of unusual sensitiveness. It frequently fails entirely. Continuous moderate currents up or down the spine do not add to k.-j.

The time element. In these experiments it soon became evident that in order to obtain the best effects, and occasionally to obtain any at all, a certain relation in time must be observed between the muscular act, or making of the circuit, and the tapping of the tendon. In the foregoing pages the expression, coincident tendon tap, is often used, and the method of completing the circuit was by a pedal or by an electric button which was pressed by the thumb, and coincided with the tendon tap as nearly as was possible with such a coarse movement. In order to make the circuit practically coincident, an electric hammer was made, so that the lightest tap with this upon the tendon sufficed to close the circuit. In repeating the experiments with this, it was found that double the number of cells could be borne, through the head or up and down the spine, as the circuit was very abruptly made and broken, and the interesting point is, that with this we failed to reinforce the k.-j. It therefore seems that the muscular action, or circuit-closing, must precede the tap, in order to reinforce it, by a period which is, as yet, undetermined, and which needs for its determination careful work in the laboratory. When a series of very quick taps, ten or twelve per second, on a tendon were employed, thus constantly exciting the muscle, it was possible at times for the subject to appreciate the interval mentioned. When the experiment of increasing the k.-j. by the application of the secondary current and the wire brush before mentioned was employed, a large portion of a second elapsed between the application of the brush to the forearm, and the reinforcement of the k.-j. This was perfectly patent to all observers, and particularly so to the subject experimented upon. It is also entirely clear, that the effect of volitional reinforcement lasts some little time, certainly in some people quite a second.

Skin reflexes. These being unquestioned reflexes, it became desirable to know if they obeyed the laws of reinforcement. Among them the cremaster reflex is the most available, and, as regards this, we think it clear that it is not increased by distant muscular acts, nor by sensations, as of pain.

Direct muscle reactions. In examining the k.-j. we were naturally led on to a remarkable series of discoveries in regard to the behavior of muscles when mechanically stimulated by a blow. The capacity of the muscle to respond to a blow varies with the muscle and the subject. It will, we think, be found that in health those persons give the best muscular response in whom the k.-j. is best. In some men a painful blow is needed to move the muscle; in others, the least tap of the hammer calls out motion. Usually the rounded conical end of our rubber percussion hammer gets the best response; but whatever is used, we make a local depression in the muscle as we strike and stretch the fibres abruptly over a limited area. What we thus do has some resemblance to the universal pull on the muscle fibres made by a blow on a tendon, but the direct muscular blow is far more rough and violent, and is a coarser and more local stimulation. The stretched muscles contract as the hammer leaves the part.

Relation to voluntary motion elsewhere. Place the bare, prone arm of a sensitive young person at rest on a cushion, with the hand dependent; strike the muscles on the back of the arm or the long supinator, so as just to get motion of the hand or of the muscle without the hand; then cause the subject to flex the other hand strongly: the muscle reaction will be at once reinforced notably. If we repeat this experiment by striking the extensors of the leg, and use violent effort in closing both hands, we shall get, in good subjects, a distinct k.-j.

All the motions which reinforce k.-j. can be shown to increase the mechanically evolved muscular reaction.

To swallow, cough, laugh, count aloud, or strongly

act with the limbs, hands, or feet, reinforces the effect of a tap on the muscle. Even the slight act of winking decisively is competent to do this.

Tension behaves somewhat as it does with the tendon-jerk. With the muscle in full relaxation we get fair results. With slight passive tension the blow acts better, and over a larger area, for obvious mechanical reasons. With extreme tension we utterly fail to be able to cause movement.

Effect of one direct muscle reaction on another. As one k.-j. does not increase another, so neither does one muscular reaction from a direct blow increase another produced at the same time; neither does the k.-j. increase the direct muscular reaction, nor *vice versâ*.

Sensation and galvanism. Rhigolene freezing and remote or near sensations (pain) reinforce direct muscle reactions (m.-j.), but not nearly so well as they do the muscle reactions from a blow on the tendon (k.-j.). Galvanism through the head increases the direct muscle act as it does the k.-j.

Points of resemblance between the direct muscle acts (muscle-jerk) and the knee-jerk.

These phenomena have many points in common, the differences are chiefly of degree, and are partly due to the fact that in the k.-j. we have a whole muscle in movement and in the muscle-jerk but a small fraction of it.

The knee-jerk seems to depend for its existence on the presence of muscular tone due to the connection of the muscle with the spinal cord, while the direct muscle reaction depends upon the presence of the muscular irritability which exists independently of any immediate connection with the spinal cord, but may be increased by toning influences coming from it.

The tap on the tendon is a distinct generalized sharp pull on the whole muscle, and is a somewhat delicate excitation easily affected by neural changes. The direct muscle blow is a strong, positive local stimulus. It may be left in existence after the knee-jerk is lessened or lost by disease. Usually what increases the one adds to the other, as we see in spastic palsy. In a case examined lately, a young man in absolute health, without a trace of disease, athletic and a good dancer, there is absolutely no knee-jerk and also no muscle act under hammer in the thigh, neither can these be called into action by any coincident act, electricity, rhigolene, etc., although in the arms the muscle-jerk is perfect for all tests.

It seems difficult to escape the conclusion that the two sets of phenomena are but varied forms of expression of one normal muscular property, dependent for its integrity upon various nutritive conditions, and for its grades of excitability upon certain relations of the muscle to normal spinal centres.

Inability to reinforce electrical contractions of muscles by the means which add to knee-jerk and muscle-jerk. It was natural to presume that if k.-j., and the muscle response to a tap, could be increased by remote movements, and sensations, and galvanism, that electricity, the third means of exciting motion, would follow the same law. This is not so; no form or degree of muscular movement obtained through galvanism or faradism could be increased by anything we could do; heat, cold, galvanism to head with volitional movements, all alike failed. It is hardly needful to detail these observations; they were varied, and made on several persons in whom it was easy to get the reinforcement of k.-j. by volitional acts or pain. The cause of this exception is not clear. It seemed possible that electric currents might interfere with the passage of the more delicate tone waves. This we tested as follows: a strong or moderate faradic primary current being allowed to traverse the supinator longus, the muscle was struck lightly with the flat end of a percussion hammer, so as to get a slight direct response; then, violent contraction of the other hand was still found able to reinforce the muscle-jerk. There are obvious fallacies in this too promising experiment, for it is impossible to be sure that all of the muscle is, so to speak, electrically occupied, unless we use an excessive current, and that interferes with the experiment, by causing too much contraction. There is, however, an interesting observation which anyone may easily repeat, and which gives one a distinct impression that electrical possession of a muscle makes its volitional acts fatiguing or difficult. Let the arm rest on a cushion, prone, faradize the extensors, so as to contract them only partially, now will to extend the hand; there is at once felt to be some unusual need for effort, some mysterious impediment. It takes an extra effort of will to use the muscle through which runs a faradic current.

It may be, therefore, that nerve and muscle texture, when under the coarse influence of electric stimulation, are less accessible to gentler tone waves.

Reinforcement of volitional acts by other volitions. If muscular movement, caused by a blow or a tap on a tendon, be capable of increase by willed motion in another part of the body, it seemed to us that one act of will should thus increase the effects of another act of will. This has been stated to be the case by Quetelet.[1] and denied by G. Stanley Hall and E. M. Hartwell.[2] Our own experiments incline us to believe with Quetelet. Muscles already fatigued by previous efforts seemed to show the most reinforcement. We hope to investigate this subject further.

Résumé and conclusions. The k.-j. varies in health, it may be exhausted by too much use, and may increase from frequent excitation.

All volitional acts, if strong enough, may increase the k.-j. of either leg, and even such small acts as winking, etc., are competent to do so under favoring circumstances.

Weak innervation of the crural nerve increases, and strong innervation of the same, prohibits k.-j.

All sciatic innervation increases k.-j.

Volitional reinforcement lasts for an appreciable time after volition ceases.

Continued violent muscular acts, as of both arms and hands, at last enfeeble the k.-j., and this enfeeblement lasts for an appreciable time.

Passive tension is not essential for the production of k.-j.

Moderate tension mechanically favors it.

Extreme tension destroys it, even in spastic cases,

[1] Sur l'homme et le développement de ses facultés, par A. Quetelet, Bruxelles, 1830, vol. ii. pp. 70, 80.

[2] Bilateral Asymmetry of Function, Mind, No. xxxii.

and this is probably mechanical in part, but also, and to a large degree, physiological.

An act of will directed to a part which is functionally inert, or to amputated parts, reinforces k.-j. Hence it is not the muscular motion which is the essential factor.

Strong or weak stimulation of one sciatic in an etherized animal, intensifies the k.-j. of the other leg; pressure upon the sciatic in man, causing pain and numbness, diminishes the k.-j. of that leg.

Elbow-, ankle-, and jaw-jerks obey the same laws as the k.-j.

One k.-j. does not reinforce the other.

Mere touch has no effect on k.-j. All abrupt impressions, as of pain, heat or cold, anywhere on the skin, increase k.-j.

Gustation has no effect on k. j.

Violent optical impressions, in sensitive cases, increase k.-j.

Nitrite of amyl has no effect on k.-j.

Etherization, if profound, abolishes the k.-j. in dogs, has less effect in rabbits.

All short faradic currents, anywhere, if strong enough to move muscles, increase k.-j.

The wire-brush, with faradism on the dry skin, is one of the most effectual of all means of addition to k.-j.

Short galvanic currents, not strong enough to move muscles, give, under certain conditions, marked increase of k.-j.

Galvanism to temples especially, but also to other regions of the head, gives large reinforcements to k.-j.

Making circuit is more effectual than breaking, and these effects soon wear out.

The negative pole to temple gives greater and more constant increase of k.-j. than the positive in same postion.

There is more effect on k.-j. from pole on temple than over leg-centres. Effect the same for either k.-j.

Galvanism to temples, with violent synchronous muscle acts, very greatly reinforces k.-j.

Long ascending spinal galvanic currents give good increase of k.-j.; descending, far less.

Moderate constant currents to spine do not reinforce k.-j.

The skin-reflexes (cremaster, abdominal) are not reinforced by muscle acts or by pain.

When the belly of a muscle is struck, the resulting contraction obeys all the laws of reinforcement which apply to the k.-j. Tension has upon it much the same influence as on k.-j. One muscle-jerk does not reinforce another.

The movement caused by electricity seems incapable of reinforcement.

Tension lessens the effect of even quite strong faradic currents as to pain and motion.

Well-known facts and the researches here stated, lead us to believe that the knee-jerk and other like responses to tendon taps are direct muscular acts; they cannot exist without that spinal contribution known as tone, which is capable of increase from a variety of causes. These muscle responses to a pull on the tendon cannot be reflexes, for the latter are inhibited by violent sensory stimulations, which are here shown to increase the k.-j. The true skin-reflexes are incapable of being reinforced by distant volitional muscular acts like the k.-j., and have a time far greater than that of the k.-j. The two groups of muscular replies to forms of irritation, therefore, differ radically. There is no reason to believe that the aid given by moderate tension to the knee-, ankle-, elbow-, and jaw-jerks, is other than mechanical; besides, it is not essential. As regards the k.-j., tension has previously been shown to be unessential. The jaw-jerk can be had when the part is without tension and is being supported by the hand. A tap on a tendon mechanically affects the tissues lying within the whole of the muscle case, but whether through the nerve ends, or more directly, is difficult to say.

The tendon tap is a more delicate mode of stimulating the muscle to act than is the mechanical blow upon its body, it is also more competent to influence the entire muscle.

The direct blow on a muscle is abrupt, violent, and local, and has two results. By abruptly depressing the muscle it makes on the muscle fibres a pull, which is limited, and to which they respond by contractions, and at the spot directly hit the immediate violence of the blow has the effect of causing an abrupt mounding of the fibres, which rise rather slowly as the longer primary fibrillar contraction ceases. This small firm elevation is not easily observed in firm muscles or in health, except in thin subjects or over bones; it lasts for some seconds and slowly disappears.

It is seen from these researches that the muscle responds to various excitations by virtue of its intrinsic irritability and its tone. Both of these vary, and their sum, when the health is highest and the body at its best, represents capacity to shorten under nerve influence, and other less natural excitations. The muscular irritability depends for its character and existence on nutritive influences. The tone is merely what might not inaptly be called tuning of the muscle. It is a final preparation for volitional excitation. We have already said that efferent spina excitations sustain its constancy, and from our own observations it seems clear that incessantly tone waves are flowing from the spine, set in motion by every sensation, and by all muscular volitions however remote.

Hence it is that when by section of nerves, disease, or other cause, we cut off the efferent influences, tone is lost and the most delicate of muscle tests, the response to tendon taps, is synchronously abolished. Clearly something in the muscle itself is the most potent excitor of tone waves, as is shown by the fact that section of the sensitive roots so affects them as to put an end to the k.-j.

After cutting the crural nerve, although tone is lost, the muscle still competently replies to the violent excitation of a blow in the peculiar manner described If now the animal be killed, circulation ceases, an with this nutritive damage come lessened respons to a blow and greater humping up of the fibres at the point struck. This latter phenomenon seems to increase for a time as the muscle gets weaker, and

are thus reminded of the fact that in the feeble muscles of thin, phthisical people it shows so remarkably well.

Next the long contraction from a direct blow becomes less, and soon only the shorter is seen. Then this too is lost. At this stage of enfeeblement, induction currents still powerfully affect the fibres which all other excitants fail to impress.

The application of the facts we have discovered to clinical research remains to be made, but assuredly they widen the field of useful possibilities in the domain of symptomatology.

It is very difficult to explain the fact that electricity, sensory impressions, and distant voluntary muscle acts increase the knee-jerk and the response to the muscle blow. If we conceive of a series of inhibitory centres extending from the mesocephalon all the way down the cord, and infer that all the agents mentioned are capable, by more or less paralyzing these centres, of releasing the active reflex groups below them, we shall be able to comprehend that the centres thus set free may, by increasing tone, give to the muscle a suddenly enlarged capacity to respond to the tendon taps or the muscle blow.

Nearly all of the facts with which we are concerned may be explained by inhibition organs and the effects produced upon them. On the other hand, it is equally conceivable that whenever a sensation reaches the cord or brain, or both, an overflow may occur which shall, by increasing the excitation of the centres, be felt throughout the body and reinforce any organs chancing to be synchronously otherwise excited from without. Under this view we conceive of the nervous force as not confined entirely to the direct paths between the centres and the muscle to be moved, but as overflowing so as to pass through numerous ganglia, adding a certain small increment to their effects when in a state of such activity as the spinal toning centres must be at all times. The tone centres thus stimulated send out a higher wave of excitability to all the muscles, and if at the time this reaches a muscle that muscle is being excited by a tap, there is an increased response.

Several facts tend to support this theory of overflow. The awkward movements of young children, and the associated movements accompanying many of our everyday acts which require great effort, may be thus explained. In excitable conditions of the spinal cord associated movements are common. Writer's and telegrapher's cramp are examples in point.

Lauder Brunton's theory of the coincidence and interference of nerve waves, as increasing or diminishing the resulting motions, as waves of light and sound are known to be influenced, may in the light of further knowledge be competent to explain more precisely the manner in which overflow acts as a reinforcing agency.

Our discoveries as to the various influences which affect the direct and indirect muscle reactions should, we think, be regarded as distinct additions to physiological knowledge. The brief speculations founded upon them may be more or less correct, and until we have examined their relations to the domain of pathology it will be difficult to decide more positively on their causes.

PERFORATIVE ULCERATION OF THE CÆCUM;

FORMATION OF FECAL ABSCESS, COMMUNICATING THROUGH THE FEMORAL SHEATH WITH THE THIGH; OBLITERATION OF THE ABSCESS CAVITY; RECOVERY.

BY GEORGE T. McKEOUGH, M.D., M.R.C.S. ENG.,
OF CHATHAM, ONTARIO.

THE following brief history of a case of typhlo-enteritis I have thought of sufficient interest for publication, not only on account of its happy and rare, if not unique, termination, but as presenting unusual symptoms throughout its evolution.

F. B., aged 47, French Canadian, blacksmith by trade. He has a good family record; both his father and mother are still living. There is no history of tuberculosis or other hereditary disease in his family. He has had several attacks of intermittent fever at different periods of his life, otherwise has always had exceptionally good health. He is married, and the father of fourteen children, seven of whom died in infancy, three of supposed tuberculosis; a daughter has had "sore eyes" for several years, and another has just recovered from a large abscess of the thigh.

His late illness began Saturday, August 9th. He had been feeling as well as usual during the day, ate a hearty breakfast and dinner, but had no desire for supper, and had a "bad taste in his mouth," for which he took a dose of "salts and senna" at bedtime. During the night he was very ill, vomited frequently, and was thoroughly purged. The following day he felt very unwell, suffered from headache, nausea, and occasional vomiting, and sent for a physician, who informed him he had a bilious attack with fever. The ensuing day he travelled 300 miles; was very weak, but there was no other marked symptom. He consulted me Aug. 12th, complaining of muscular weakness, languor, headache, pains in his back and limbs, and failure of appetite. The tongue was coated; pulse 80, and temperature 99.6° F. There was no complaint of abdominal symptoms, nor had there been any epistaxis. He was ordered a quinine mixture, to remain quietly at home, and to restrict himself to a milk and water diet.

Two days subsequently (Aug. 14th) I visited him, and found symptoms had not improved; suffered from severe frontal headache; general weakness, malaise, and some soreness over his bowels, which were slightly tympanitic; pulse 89, temp. 101° F. He was ordered to bed and the quinine continued, my diagnosis wavering between typhoid and remittent malarial fever.

Aug. 16.—P. M., temp. 102° F., pulse 80. He has a dull abdominal expression, sunken cheeks, intellect somewhat clouded, breath foul, resembling the peculiar, heavy, offensive breath of typhoid patients; still complains of headache, but its severity has abated; slight soreness in the abdomen, and some pain in the region of his right hip, but its precise locality he is unable clearly to define. His bowels are open, but there is no tendency to diarrhœa. There is neither tremor nor rose-colored rash to be seen.

20th.—During the past few days his temperature has varied from 100° to 101° F. in the morning, to

102 to 103° F. in the evening; his pulse has never exceeded 90 per minute. The headache has ceased, but he has complained of great pain in the upper part of his right thigh, the pain being most severe along the line of Poupart's ligament. Pressure increases the pain, and the tenderness seems greatest at the point where the femoral sheath emerges from under the ligament. There is some abdominal tympanites and a fulness which is uniformly distributed, but no hardness or tenderness on pressure in any part of the abdomen. After careful palpation I thought increased resistance was slightly more marked in the right inguinal region than in the left. The right thigh is flexed, as is usual in typhlitis, and complete extension cannot be endured. Movements of the entire limb in the flexed position, within a limited area, do not augment his sufferings, nor does a rap on the heel increase the pain. The manipulations were undertaken to detect or eliminate any joint affection, the cause of the pain being obscure. He reclines upon the painful side, and any attempt to move him from this position causes unbearable suffering. Opium had to be administered freely, hot fomentations were first applied, afterward a few small blisters to the painful parts. Quinine and dilute nitro-muriatic acid were also given. The opium did not cause constipation.

26th.—The pain and tenderness are subsiding, opium not being now required, but the thigh, especially the upper third, has enlarged to nearly double the dimensions of the left limb; to a less degree, the lower two-thirds has also increased in size; but below the knee there is no swelling. There is neither redness, nor any palpable indication of an abscess pointing; deep pressure along the course of the femoral vessels in Scarpa's triangle is painful; he still keeps the thigh flexed, and lies partially upon the right side.

For a day or two past he has had a diarrhœa with ochre-colored dejections, which he regards as brought on by drinking heartily of beef-tea, the diarrhœa ceasing on a return to milk diet. This occurrence revived, in my mind, the idea of typhoid fever; it having been pointed out by Brieger,[1] that the typhoid bacilli when cultivated in a peptone solution produce no poison, but when cultivated in an infusion of meat, induce its decomposition, with the production of two poisonous alkaloids, both of which cause diarrhœa. This probably accounts for the clinical fact that beef-tea and its congeners are so frequently inadmissible in typhoid fever, developing diarrhœa when that symptom does not exist, or increasing such a condition if it be present. With this exception, there was no pronounced disturbance at any time of the function of the alimentary canal. There are none of the ordinary symptoms of typhlitis or perityphlitis present, such as fulness, tenderness, pain, hardness, or the presence of a tumor in the cæcal region. His temperature varies from 100° F. A.M. to 102° F. P.M., pulse 80. There are neither chills, sweats, rash, tremor, nor are there sordes upon the teeth.

Sept. 6.—The swelling is gradually subsiding, and tenderness likewise, although there is a feeling of fulness along the course of the femoral vessels in the upper part of the thigh, and severe pressure causes pain. Cannot fully extend his thigh as yet, but lies on either side. No desire for food. Temperature still elevated.

12th.—I had not seen the patient for several days until to-day, when on examining his leg in conjunction with Dr. T. K. Holmes, a tumor the size of a small orange was seen about the junction of the upper middle third of the thigh on its inner and anterior aspect. The lump fluctuated, was tympanitic, and pressure caused it to subside with a gurgling similar to that heard in the reduction of a hernia. Allowing the limb to hang down or pressure upon the abdomen caused its reappearance, while alternate pressure upon the tumor and abdomen produced loud gurgling sounds. The air could be clearly felt passing to and fro. Upon elevating the limb and using gentle pressure, the tumor almost entirely disappeared, leaving, however, a few hard irregular masses about the size of acorns; some small, diffused, ill-defined masses could also be felt in Scarpa's triangle. Temperature 100° F. Pulse about 100. The diagnosis was now definite: there was evidently a perforating ulcer of the cæcum, doubtless situated in its posterior wall. which, according to Bartholow,[1] is the most common position for its occurrence; out of fourteen cases analyzed by him, in twelve the accident occurred in that portion of the gut not covered by peritoneum. A fecal abscess was the result, the contents of which must have followed the course of the iliac and femoral vessels passing down between the peritoneum and iliac fascia, beneath Poupart's ligament, being confined probably to the sheath of the vessels until the resistance became so great as to cause pointing toward the surface. Inquiry was made as to the possibility of the patient having swallowed any foreign body previous to his illness, but the result was negative.

Pads of absorbent cotton were placed about the upper anterior and inner portion of the thigh, extra pads being laid along the course of the vessels, and a flannel bandage applied from the foot upward to the thigh and abdomen, pressure being firm but equable. To remain in bed with leg elevated, and the strictest quiet to be maintained. Milk or buttermilk for diet, and a mixture containing nitro-muriatic acid and tinct. calumbæ was given.

18th.—He is gaining strength, suffers no pain, sleeps well, appetite improving, bowels open daily, and he is in good spirits. In reapplying the bandage, faint gurgling sounds were heard when the bandage reached the upper fourth of the thigh.

Oct. 1.—His temperature has been normal for the past few days, his appetite is good, and he is renewing strength daily. He was permitted to leave his bed to-day, and to use crutches. Not the slightest gurgling was heard in applying the bandage to-day, the small hard masses had disappeared, but a decided thickening could be felt along the inner side of the femoral vessels, for about an inch and a half below Poupart's ligament.

[1] Practitioner, August, 1885.

[1] American Journal of the Medical Sciences, October, 1866.

17th.—The bandage was omitted to-day; the thickening near the upper part of the femoral sheath was found to have disappeared; the right limb is greatly emaciated, and out of all proportion to the remainder of the body.

He gradually gained strength, used crutches for two or three weeks on account of the feebleness of the right leg, and for some weeks after discarding his crutches he favored this leg, limping slightly when walking. He was seen November 28th, and seemed quite recovered, and almost as strong as ever, having returned to his trade. The termination of this case was certainly a fortunate one, and, I think, may be in part attributed to the absolute rest maintained throughout the course of the disease, and to the avoidance of purgatives, two essential factors which cannot be too rigorously attended to in the treatment of all obscure abdominal affections of an acute character.

NOTES OF THIRTEEN CASES OF TUBERCULAR MENINGITIS.[1]

BY J. H. MUSSER, M.D.,
PHYSICIAN TO THE PHILADELPHIA HOSPITAL

ALL of the cases were observed in private practice, hence the lack of detail of symptoms, such as temperature, etc. They occurred in a period of six years. Nine of them were in the writer's private practice, two in institutions under his care, and two in the practice of medical friends. It may be considered a disease of frequent occurrence, and is more commonly met with than many other diseases of recognized frequency, as, for instance, forms of liver disease The nine cases occurred in a practice ranging from 50 to 400 families yearly, during the six years. For every case of tubercular meningitis, the writer has had twenty-five of phthisis. During the same period one case each of tubercular peritonitis and intestinal tuberculosis have been under his care. In later years the disease has been less frequently seen, corresponding with the social improvement of the practice. In the first half, six cases were observed. In the latter half, the remaining ones. The mortality table of the "Homes" to which the writer has been physician, present some interesting features in this connection. In one Home of 180 boys, aged from three to sixteen, and 30 adults, but three cases of tubercular meningitis occurred in five years. In a Home for 24 colored children of both sexes, mean age seven years, the disease was not observed in four years In a third Home for children of both sexes, about eighty in number, in the records of twelve years, no death occurred from this disease. During the same period of observation of these nine cases, five cases of hydrocephaloid disease, one of cerebro-spinal meningitis, and two of syphilitic meningitis were observed.

Causes: Seven of the cases were males, and six females, showing that sex exercises no causal influence. The ages ranged from seven months to fourteen years in twelve cases. One was thirty-two. Six of the patients were under five years, four between five and ten, and two between ten and fifteen. The ancestors of nine had tuberculosis in some form. In two other instances the children of the same generation had some tubercular affection. In only two cases was there no antecedent or coincident history of tuberculosis in the family. One of the patients, aged seven months, was nursed by a mother whose tubercular disease antedated her pregnancy.

The hygienic surroundings in the large number of cases were quite fair. Two alone could be pronounced bad. One child had been weaned early in life, and improperly fed afterward. The previous health of all save one or two was bad. Some remote local inflammatory foci, either of simple or specific nature, could be determined. In one, aged fifteen months, the bronchial and mesenteric glands, after a whooping-cough and diarrhœa, were diseased; asthma and bronchitis, with enlarged bronchial glands, no doubt, preceded in another; hip-joint disease, suppurating cervical lymphatics, chronic bronchitis, and phthisis, respectively, preceded in four cases. Very poor health in one instance, and "weak" lungs in another, also preceded. In one, the health had apparently been good; in two the state of the health was not noted. Exposure to the sun was thought to be the cause of the twelfth, but the lid was always fragile, and had diarrhœas. The nursing baby completes the list—she was always delicate.

Clinical Course: In general, it may be said to be irregular. In six cases the periods of invasion, excitation, and depression could be traced. In two instances the stage of invasion or the premonitory symptoms was absent entirely. In the other cases the stages were "mixed."

The following summary indicates the mode of development of the entire series. Case I. was a girl aged sixteen months; antecedent cause, whooping-cough and tabes mesenterica, slight general spasm, followed in a few hours by convulsion of right side of body with aphasia. In Case II., boy aged four, with asthma, etc., there was loss of flesh for four weeks, intermitting headache ten days, vertigo three days, was peevish and restless at night. Case III., girl aged ten years, had for one year headache and vertigo, with extreme emaciation (cerebellar tumor). In Case IV. there were loss of flesh, debility, restlessness and poor appetite for several weeks. The course of the fifth was not known, while the sixth had been ill ten days definitely; for some time loss of flesh with pain in the left temple, sleeplessness and constipation being present. Sharp paroxysmal headache tormented the seventh case, a youth of nine, for three days prior to the meningitic explosion. Until twenty-four hours before very active symptoms occurred, the eighth case, an infant under two years, was considered in perfect health. Prolonged lassitude, fretfulness, and some emaciation, preceded the illness of Case IX., a boy of eight. For four weeks the tenth case, a precocious little girl five years old, suffered from symptoms not unlike malaria—languor, emaciation, fretfulness, irregular intermitting fever, restlessness at night, poor appetite, without vomiting or constipation. The eleventh case had phthisis, but observed that his customary hectic had quitted him two weeks before the development of headache and vertigo, which symptoms antedated the active brain symptoms

[1] Read before the Philadelphia Neurological Society, January 25, 1886.

by four days. The twelfth case did not thrive as a nursing baby should, and vomited frequently. A convulsion was the first warning of cerebral trouble. The thirteenth case, a little girl, lost appetite, was peevish, slept poorly, was feverish and became emaciated for three weeks before the cerebral symptoms developed. She had lymphatic enlargement in the neck and abdomen. Emaciation, debility, fretfulness, night-restlessness, irregular febrile movement, disorders of the gastro-intestinal tract and headache were, therefore, the chief premonitory symptoms in these cases, emaciation being the most frequent and most marked.

An analysis of the phenomena of the first and second stages would be tedious and without practical value. Reference in the succeeding notes will be made to some salient groups of symptoms, present more or less in both stages, and to peculiar manifestations of common symptoms. *Headache, motor* and *sensory irritations,* and *palsies* occurred in all the cases. In a few, the *headache* was distinctly intermitting. The *spasms* and *palsies* of groups of muscles were irregular in respective cases, as to order or frequency. Hourly change in the state of the muscles was common, and the same may be said regarding sensation. Not only does this apply to alterations of function of spinal but also of peripheral nerves. Convulsions (partial, unilateral, or general), delirium, and coma were present, but presented no peculiar feature.

Special senses: Total blindness was early in one case; impairment of vision in five; optic neuritis was recorded in three. The state of the pupils was not of special import—in one instance there was irregularity in size in the second stage. In the first stage they were not affected, save contracted in one instance, and fixed, in a dilated state, in another. Dilatation was the rule in the second stage. Nystagmus was observed in one case. Purulent conjunctivitis occurred in eight cases, in the second stage usually, and in two instances was unilateral. Ptosis was present in only one case.

In five instances local erythema and general flushings were noted. An urticaria-like rash was seen in three instances. In the later stages pallor or a bluish hue of the face was observed. A unilateral mottling of the extremities was observed. Emaciation was marked and persistent in the prolonged cases, nine in all. Fever was present in the first stage in seven cases; in the second, in nine; intermitting in type, often with irregular paroxysms. Hyperpyrexia was noted in one. The *pulse* was slow seven times in the first stage; irregular or intermitting in four. In the second stage it was usually quickened, small, rapid and feeble; twice, slow and irregular. It was never wiry or corded in either stage.

Vomiting occurred but three times in the first stage; once only in the premonitory stage, and once only in the final stage. Constipation was seldom observed—three times in the first, twice in the second stage. Diarrhœa was excessive once. Offensiveness of the *breath* was very frequent and occurred chiefly in the last stage, but was so marked at first, in three cases, as to be noted. In nine instances the tongue was heavily coated. The scaphoid abdomen occurred at varying periods: once in the first stage, seven times in the second stage, while three times it is recorded absent; twice there is no record. Respiratory symptoms: first stage, irregular or Cheyne Stokes, four times, rapid twice, slow once. Second stage, Cheyne-Stokes twice, rapid six times.

Remissions of a decided character were noted twice; after the development of the most grave symptoms, a period of improvement led to hopes of recovery.

Duration: Of premonitory symptoms, unknown twice; prolonged, once; one year (cerebral tumor), once; in three cases, about four weeks; in two, ten days; in one, three days; in another, twenty-four hours; and in two the first stage developed at once.

First stage: Twelve hours, 2; four days, 2; five days, 2; ten days, 2; eleven days, 1; thirteen days, 1; unknown, 3.

Second stage: Twenty-four hours, 1; seven days, 1; five days, 3; forty-eight hours, 1; six days, 1; eight days, 1; four days, 2; nine days, 1; unknown, 2.

Entire duration: Thirty-six hours, 1; four days, 1; seven days, 1; twelve days, 2; fifteen days, 2; eight days, 1; fourteen days, 1; eleven days, 1; unknown, 3.

The difficulty of estimating the duration is evident to any one. It can only be said that a short first stage, in all the instances, determined a short second stage.

A post-mortem examination was held in four of the cases. In two the disease was largely localized, once in the cerebellar region, again over the right frontal convolutions, the presence of the tubercle causing during the life of each the symptoms due to localized cerebral irritation at these points.

Summary. From the above we learn that *tubercular meningitis* may be considered a disease (1) of frequent occurrence, in the middle and lower classes especially; (2) more frequent than other localizations of tuberculosis, except the pulmonary; (3) and much more frequent than other varieties of meningitis.

That the *predisposing causes* are *age,* and a hereditary tendency to tuberculosis. That the *exciting cause* is a focus of infection, inflammatory or "cheesy," which can almost always be found in some part of the body.

That the premonitory symptoms of note are emaciation, fretfulness, gastro-intestinal disorders, irregular fever, and headache. That the symptoms of the fully developed disease, worthy of note, aside from headache, spasms, and palsies, are purulent conjunctivitis; erythema, and other vascular changes of the skin; an offensive breath; the scaphoid abdomen; irregular fever and alterations in pulse and respiratory rhythm. Vomiting and constipation were not marked phenomena in the cases of the series. The expression of the face and the decubitus of the patient did not differ from the usual accounts. That the premonitory symptoms may be absent entirely or of very variable duration.

That the symptoms of the first stage continue six days (average); of the second stage, four and one-half days (average); and the entire duration lasts on an average ten days.

We have learned further, from the above observa-

tions, that the diagnosis can be made by attention to the following points. The age; the hereditary tendency; the presence of a caseating focus or the history of a disease likely to produce such a focus; the presence, in addition to cerebral symptoms, of two or more groups of the symptoms detailed in the preceding summary, and the appearances of the eye-ground.

We are aware that these conclusions differ, in many respects, from those presented in the text-books. They are deduced from the above series, and are believed to be substantially correct. It is to be regretted that no light can be thrown on the interesting relations of the tubercle bacillus. These studies were made before its discovery, however.

3705 Powelton Avenue.

MEDICAL PROGRESS.

The Sound Accompanying the Single Contraction of a Skeletal Muscle.—Drs. Herroun and Yeo have made a series of experiments on this subject. The sound heard on auscultating a continuously contracting skeletal muscle is generally ascribed to certain vibrations of the active tissue, of such periodicity as to give rise to a tone of some thirty-six to forty waves per second. The theory that the normal muscle sound might be said to have a relationship to a musical tone has been always used as an important link in the evidence tending to prove that normal nerve impulse is intermittent, and that continuous voluntary contraction is composed of summated single contractions, like the artificial tetanus produced by interrupted stimulations. The fact that the heart beat is but a single contraction is commonly urged against the view that the systolic sound is due to muscular tone, because it is commonly accepted that the sound produced by contracting skelatal muscles depends upon the regular variations of tension of the tetanic contraction. Their conclusions were as follows: 1. That a single contraction of a skeletal or heart muscle gives rise to motions or vibrations which evoke the resonant tone of the membrana tympani. 2. That the tone heard in voluntary contraction is no evidence of distinct or regular vibrations in the muscle, but merely of motions, regular or irregular, which produce the vibration of the membrana tympani. 3. That the tone heard in voluntary contraction is, therefore, no evidence of regular discontinuity of natural nerve impulses, but simply depends upon trembling movement due to variations either of force or distribution of stimulation. 4. That the objection to the first heart-sound being a muscular sound, because the systole of the heart is a single contraction, is not valid, since the single contraction of a muscle causes motions or vibrations which call forth the resonant tone of the ear. —*Journal of Nervous and Mental Disease*, Jan. 1886.

Resorcin in Gonorrhœa.—Letzel finds that three per cent. solutions of resorcin are sometimes irritant to the urethra, and recommends that the treatment be begun with a two and a half per cent. solution, and increased according to the tolerance. In chronic gonorrhœa four per cent. solutions are usually borne without trouble. The average duration of treatment, in acute cases, was about twelve days; in chronic cases fourteen to thirty-two days. Stress is laid upon the necessity of employing chemically pure snow-white resorcin, which is entirely colorless in solution. It is dissolved in distilled water, kept well corked in opaque glass bottles, and it is recommended that not more than three ounces of the solution be ordered in one prescription.—*Centralb. f. d. med. Wiss.*, Dec. 19, 1885.

Ratio of Increase of Height to Increase of Bulk in the Child.—Some remarkable observations have been recently made by the Rev. Malling Hansen, principal of the Danish Institution for the Deaf and Dumb, on the progressive increase in height and weight of children, 130 of whom were under his charge. Of these, seventy-two were boys and fifty-eight girls, and they were weighed in batches of twenty, four times daily: in the morning, before dinner, after dinner, and at bedtime. Each child was measured once a day. The weighings and measurements extended over a period of three years, and the results showed that the increase in the bulk and height of the body does not proceed at a uniform rate throughout the year. Three distinct periods, with some minor variations, were observed. In regard to bulk, the maximum period extends from August until December; the period of equipoise lasts from December until about the middle of April, and then follows the minimum period until August. In regard to height, the maximum period corresponds to the minimum period of increase in bulk. In September and October a child grows only a fifth of what it did in June and July. So it appears that during the autumn and the beginning of winter the child accumulates bulk, but the height is stationary. In the early summer, on the other hand, the bulk remains nearly unchanged, but the vital force and nourishment are expended to the benefit of height. When the body works for bulk there is rest for growth, and *vice versâ*. M. Hansen has observed a similar ratio of increase of bulk to increase of height in trees. In regard to the minor variations observed, it is probable that they are dependent—in part, at least—upon the external temperature, so that when this runs up there is marked increase in weight, whilst a diminution of weight occurs with a fall of temperature. M. Hansen's observations were communicated to the International Medical Conference, held in Copenhagen in 1884, and are undoubtedly of considerable importance. Similar observations have been made both by Dr. Percy Boulton (whose results were given in our columns in 1880) and by Dr. W. R. Miller, surgeon to the West Riding Convict Prison. Dr. Miller experimented on about 4000 prisoners for thirteen years, and obtained results that differ sensibly from those of M. Hansen; for he found that the season of maximum increase in weight in adults is from April to August, and the period of minimum increase in adults from September to March. Dr. Miller found the body became heavier in summer and lighter in winter, and he attributes the loss of weight to the more active excretion of carbonic acid gas in the colder months.—*Lancet*, Jan. 23, 1886.

The Synthesis of Cocaine and its Homologues.—By treating anhydrous ecgonin with benzoic oxide and methyl-iodide for ten hours to 100° in a sealed tube, Merck has produced cocaine. Substituting ethyl-

iodide, the same reaction gave him its ethyl homologue, which crystallizes from alcohol in brilliant prisms fusing at 108°–109°. Platinum chloride produces, even in very dilute solutions of its salts, a yellow precipitate soluble in hot water and crystallizing on cooling in brilliant yellow rhombic plates. Ladenburg proposes for it the name cocethyline.—*American Journal of Science*, Feb. 1886.

Tobacco Amblyopia.—In a tabulated report on twenty cases of tobacco amblyopia, Dr. G. Hartridge presents the following methods of diagnosis and treatment: The chief points relied on in the diagnosis were: (*a*) Rapid failure of sight, with no ophthalmoscopic or other change to account for the great loss of vision; (*b*) central color scotoma; (*c*) excessive smoking. Of the twenty cases, all improved considerably, and in thirteen complete recovery may be said to have resulted. In one instance the patient was a woman (the only one that has ever come under his notice suffering from tobacco amblyopia), another was a teetotaler, and four chewed as well as smoked; but in no instance has he met with a case of amblyopia in a person who used tobacco for chewing only.

As regards treatment, the essential point was the total discontinuance of smoking, instead of diminishing the quantity and quality of the tobacco, as suggested by some writers. In half the cases strychnine was administered, in the other half a placebo, with apparently equally good results. Galvanism was tried in three cases, but with no appreciable effect. After recovery, three or four pipes of mild tobacco daily were allowed, but a caution was given that excessive smoking would be likely to produce a return of the amblyopia. In his experience optic atrophy has never resulted.—*Brit. Med. Journal*, Jan. 30, 1886.

Hippurate of Sodium.—Dr. Bon, in applying Garrod's observations, that sodic hippurate has the property of decomposing uric acid, has recommended the following formulæ for use in affections dependent upon the uric acid diathesis:

1.—Hippurate of sodium	. . .	10 parts.
Carbonate of lithia	. . .	3 "
Glycerin	. . . .	30 "
Cinnamon water	. . . .	500 "

Dose, f℥iv, four times daily.

2.—Hippurate of sodium	. . .	12 parts.
Chlorate of potassium	. . .	3 "
Simple syrup	. . . .	40 "
Peppermint water	. . .	400 "

Dose, f℥iv, four to six times daily.—*Les Nouveaux Remèdes*, Jan. 1, 1886.

The Mental Condition in Hypnotism.—In the work by Dr. D. Hack Tuke on "Sleep-walking and Hypnotism," he brings together very much that is interesting. He touches slightly on the injurious effects of hypnotism upon the subject. It is to be regretted that this matter, which is an exceedingly practical one, has not received more attention, either at the hands of the author or others.

He sums up the chief points relative to the mental conditions present in hypnotism as follows:

1. There may be consciousness during the state of hypnotism, and it may pass rapidly or slowly into complete unconsciousness, as in the somnambulistic state; the manifestations not being dependent upon the presence or absence of consciousness, which is merely an epiphenomenon.

2. Voluntary control over thought and action is suspended.

3. The reflex action, therefore, of the cerebral cortex to suggestions from without, so long as any chance of communication is open, comes into play.

4. While consciousness is retained, the perception of reflex or automatic cerebral action conveys the impression that there are two egos.

5. Some of the mental functions, as memory and imagination, may be exalted, and there may be vivid hallucinations and delusions which may persist after waking.

6. Unconscious reflex mimicry may be the only mental phenomenon present, the subject copying minutely every thing said or done by the person with whom he is *en rapport*.

7. Impressions from without may be blocked at different points in the encephalon according to the areas affected and the completeness with which they are hypnotized; these are impressive or suggestive whether by gesture or word or muscular stimulus, may take the round of the basal ganglion only, or may pass to the cortex, and having reached the cortex, may excite reaction and reflex muscular action with or without consciousness, and wholly independent of the will.

8. There may be, in different states of hypnotism, the opposite conditions of exaltation and depression of sensation and the special senses.—*Journal of Nervous and Mental Disease*, Jan. 1886.

Iliac Abscess opening in the Intestinal Cavity.—Dr. Garriga Y Puyg, of Madrid, relates the case of a child, about two years old, in whose right buttock was a painful tumor, resulting from a fall, about one month previously. A purulent diarrhœa confirmed the diagnosis of a pelvic abscess opening in the intestinal cavity. The perforation was evidently quite small, for the tumor constantly increased in size. In a few days manifest fluctuation appeared immediately behind and below the great trochanter, the incision of which caused the exit of a large quantity of fetid pus, mixed with gas of a stercoraceous odor. The cavity was washed out with a solution containing one per cent. of carbolic acid and five per cent. of alcohol, thrice daily. The fistula closed after one month of this treatment, and the recovery was complete.—*Gazette Hebdomadaire*, December 19, 1885.

Influence of Pregnancy on the Progress of Mental Diseases.—The lately recorded personal observations of Perreti accord with the generally accepted conclusions that the appearance of pregnancy in the course of a mental disease usually exercises an unfavorable influence.

If the prognosis is not thereby rendered fatal, it is at least rendered more grave and doubtful; and the more so, the later the appearance of the pregnancy in the course of the malady. Patients in the state of dementia are not notably influenced by the physiological accident in question, though usually a period of superexcitation appears, after parturition, which last is usually normal.—*L'Encéphale*, Dec. 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET.
PHILADELPHIA.

SATURDAY, FEBRUARY 20, 1886.

OPERATION TO RESTORE NERVE FUNCTION.

IN THE MEDICAL NEWS of December 19, 1885. attention was called to a remarkable case of successful nerve-section, by Surmay, after excision of a piece three-quarters of an inch long. In this case, while the result was astonishing and better than had ever been obtained before, it was possible to bring the divided portions of the nerve into immediate contact; and it is the rapidity with which the function was restored which excites comment, and not the mere fact that it was restored. But there is another class of cases of nerve injury, in which so much tissue has been lost or injured that the gap can only be filled up by some method less simple than suturing. How to deal with these cases has long been a puzzling question to surgeons. In a recent paper, "Ueber die operative Behandlung von Substanzverlusten an peripheren Nerven," contributed to the *Archiv für klinische Chirurgie*, Bd. xxxii. Heft 4, TILLMANNS, of Leipzig, presents a very interesting review of what has been done, experimentally and practically, in this way, and gives an account of a case of his own in which the best results followed the employment of a method which he recommends.

The operations which have thus far been suggested may be summed up as follows:

1. Transplantation of a piece of nerve from an animal of the same or of another species. This has been done successfully in animals by Philipeaux and Vulpian, and others, and most recently by Gluck. But the result is uncertain, and the conditions favorable to success are not yet clearly defined, although this plan certainly invites further study and experiment. It has once been employed in man by P. Vogt, and once by Albert, with apparently negative results.

2. Nerve-grafting, as proposed by Létiévant in 1863. This method consists in uniting the peripheral end of a divided nerve to the continuity of a sound one in a way indicated by its name. It has been employed once in the human subject by Despres, the result being good, but, as Tillmanns points out, open to the suspicion that it may have depended more upon vicarious action of unimpaired parts than upon restoration of lost function in the nerves and muscles previously affected.

3. A modification of this method consists in joining a nerve divided at a lower point to the continuity of one severed higher up, and then uniting the distal end of the latter to the proximal end of the former, while the proximal end of the second nerve is joined to the continuity of the one divided at a lower point. This complicated method appears never to have been practised either upon man or upon animals.

4. Vanlair, in 1882, reported that he had secured regeneration of a nerve in dogs by securing the divided extremities in the ends of a decalcified bone drainage tube. Here the tube seems to have served simply as a protection to the developing nerve fibres as they proceeded from the proximal end.

5. Löbker, in one case, resected a piece of both bones of the forearm, and sutured the soft parts, including the median and ulnar nerves, with an excellent result.

6. Létiévant, in 1872, attempted to unite the divided median and ulnar nerves of a man by cutting down on them, dissecting up from each end of both a pedunculated flap, and joining the flaps by sutures, so as to fill up the gaps in the nerves. This operation did not improve the condition of the patient. Nevertheless, Tillmanns is convinced that it is worthy of imitation, and has employed it in a single case, which he reports in the paper before us. His patient was a woman, twenty-three years old, who had been wounded with a scythe about two inches above the wrist, on the volar side of the forearm, with complete division of the median and ulnar nerves, followed by paralysis and atrophy of the muscles to which these nerves are distributed. Four months after the date of the injury, Tillmanns cut down through the scar, and found the ends of the nerves separated by a gap about an inch and three-quarters wide. He freshened the ends, dissected up a flap from each of them, and joined these flaps with two fine catgut sutures. A similar method was used to join the ends of the divided tendons. The wound healed by first intention. Passive exercise and electricity were energetically employed, and the functions of the nerves and muscles were almost fully reëstablished in the course of fourteen weeks. The patient's condition a year after the operation was so

good, that she wrote Dr. Tillmanns a letter with the previously paralyzed hand, which she said was as good as the other, except that sensibility was not perfect at the ends of the second and third fingers.

It is not surprising that such a result should lead Tillmanns to recommend this method of operating to others. To this motive may also be added the inducement offered by a knowledge of the mechanism of nerve regeneration. This is not so exact as might be wished; but it seems probable that nerves are regenerated by the outgrowth of tissue which proceeds from the proximal end of a divided trunk, and that any interposed material can only serve as a sort of scaffolding or guide for the advance of this tissue. It would appear rational, therefore, to use for this purpose an absolutely homologous material, as well as one which is vitally connected with the part to be renewed. It would certainly appear advisable to try this flap method in cases in which the ends of a divided nerve cannot be brought together, before resorting to so radical a procedure as cutting out a piece of bone to permit of their approximation, as was done by Löbker. But, in any case, the facts briefly indicated above, together with the well-known power of regeneration in nerves, are calculated to encourage surgical interference in cases in which nerves have been accidentally divided, or in which segments have been removed by operation. At the same time it is important, in judging the result of an operation, to bear in mind what may happen, in the way of restoration of function, without any operation whatever. If due allowance be made for the part which may be played by the natural regenerative power of nerves, and for the deceptive effects of the vicarious action of muscles and nerves, it may be hoped that a judicious application of the present resources of surgery will lead not only to a better understanding of the intricate problems of the morphology and physiology of the nerves, but also to the great advantage of those who have sustained injuries of the class described.

HEREDITARY CHOREA.

THE hereditary transmission of disease, or of the tendency thereto, is nowhere better illustrated than in many nervous and muscular affections. We can recognize an entire group of so-called "family diseases," of which progressive muscular atrophy, pseudo-hypertrophic paralysis, and hereditary ataxia are the most striking examples.

A hereditary tendency to chorea is well recognized in children, but the remarkable record given by DR. PERETTI, in the *Berliner klin. Wochenschrift*, No. 52, 1885, is probably unexampled in the history of the disease. Mrs. N. suffered from a mental affection and choreic movements, and there was a history of similar troubles in her parents and grandparents. Two of her four children, Mrs. A. and Anton N., when adults, suffered for years with chorea, and the latter became insane. Of the five children of Mrs. A., three became choreic, one son has tremors, and one is insane; while of the ten children of Anton N., six developed chorea; so that, in all, twelve members of the family have been afflicted. The disease appeared in each case in middle life, after forty years of age, and has persisted. In several members of the family insanity followed, or came on at the same time with the development of the movements. The author regards the affection as true chorea of the chronic form described by Sée, which affects adults or elderly people, and persists for years without any relief from treatment. Peculiarities which separate this form from the common infantile disease are the diminution of the motion during intentional movements, and the chronic, incurable course; and it is not improbable that when the morbid anatomy of the disease is known, it will be found to be more closely allied to those disorders of coördination depending upon sclerotic changes in the brain than to true chorea.

This is doubtless the same affection as has been well described as hereditary chorea by DR. CLARENCE KING in the *New York Medical Journal*, vol. i., 1885. In the family which he observed, the great grandmother of his patient had ten children, four of which were sufferers. Of three of these the history is incomplete, but they had children who developed chorea. Of the fourth child the history is well known. He had nine sons and daughters, only one of which was affected, and he has five children, of which three were choreic and two healthy. The disease never manifested itself before the twenty-fifth or thirtieth year—although it often appeared later—in one instance, not until the fiftieth year. In the *Medical and Surgical Reporter*, 1872, DR. GEORGE HUNTINGDON, of Pomeroy, Ohio, gave an excellent account of hereditary chorea as it existed in certain families of the east end of Long Island. The late appearance and the tendency to mental disorders, together with the hereditary nature, are exceedingly well portrayed.

IS HE DEAD?

MOST of us remember the mythical dog of the distich, who, while he lived,

> "Lived in clover,
> And when he died, he died all over."

The dog was mythical, not on account of his habitat, but because no vertebrate is subject to the synchronous death of all its parts, except as a result of instant annihilation. Were we, however, to decapitate the living subject of the rhyme, there would be before us, after the last convulsive struggle, that

which to the layman is a dead dog and nothing more. We, of course, know that in that limp body there still lurk all the potential energies of life, and that were the vessels of the severed head filled with a stream of bright arterial blood, the drooping lids would rise to disclose eyes roving, perhaps, from point to point in search of the assailant. The stream is stopped, and once again the dog is dead. We open the abdomen and do not cause thereby the slightest twitch of pain. The heart has ceased to beat, and not the faintest gasp is heard or seen, and yet before our eyes there slowly writhes the warm and most uncanny gut. The opened belly cools, the movement dies away, but blood removed from the now well-filled veins still shows, when microscopically examined upon the warm stage, the amœboid movements of its living leucocytes.

And even now there still remains intact one vital attribute. The muscles, lax and inert because deprived of those great central motor forces which were, perhaps, the first of all to fail, will yet respond to an electric stimulus. It was through a knowledge of this fact that Rosenthal was enabled to diagnosticate an apparent death of forty-four hours' duration and thus prevent a premature burial. Richardson, of London, observes that unless the body be previously warmed, the test may fail.

Such methods were not at the disposal of our forefathers, and for them the cessation of respiration and circulation heralded inevitably the coming of the end. The former condition was determined by the mirror or feather at the mouth or nostrils, or by balancing a vessel of water on the seemingly motionless chest. That such signs are of value only when positive, is sufficiently shown by the fact that respiratory movements are not thus discernible in hibernating animals. Apart from the finger on the pulse, the heart's arrest and its attendant train of effects were shown by the unreddened tip of the tightly ligatured finger, by the non-oxidation of the bright needle inserted in the flesh, by the disappearance of the normal translucency of the hand, by the uncoagulable bubbly serum in the heat vesicle produced post-mortem, and by the absence of congestion on the subcutaneous injection of ammonia. There is, also, a series of neuro-muscular phenomena of much importance: the simultaneous relaxation of the sphincters, the dropping of the jaw, the flexion of the thumb against the palm, and the absence of pupillary response to light or atropia. Then came Bouchut's ophthalmoscopic observation of the development of gas in the retinal vein immediately after death—an observation of great importance if fully confirmed.

Until some thirty years ago, however, the symptom of muscular rigidity when coincident with other mortuary signs, meant but one thing. The *rigor mortis* was the stiffness of death, and indicated not only that the individual was beyond recovery, but that the muscles themselves were dead, and their myosin coagulated by a demonstrable post-mortem development of acid. Then were published, almost simultaneously, the observations of Brown-Séquard and Stannius. The former, using as material two executed criminals, showed that in, respectively, thirteen and fifteen hours after death, the rigid limbs of these subjects, on the injection of arterial blood in their vessels, became lax and responsive to electric stimulation. The analogous experiments of Stannius demonstrated the apparent paradox of temporary artificial rigor mortis, induced in a limb by the exclusion therefrom of arterial blood for a space of from two to four hours, and dissipated by the reëntrance of the normal blood stream. Kühne, who repeated these experiments, and whose results have for some time been regarded as final and conclusive, maintained that here the rigor was incomplete, and that a more prolonged stoppage of the arterial current would have produced a rigidity which could in nowise be dissipated, and which was dependent upon the death and coagulation of all the muscle fibres of the limb.

But now there reach us the reports, fragmentary, unconfirmed, and lacking in detail, of a recent discovery made by Brown-Séquard, which appears to prove that *muscles in a state of cadaveric rigor remain endowed with the vital attribute of contractility up to the appearance of putrefaction.* By means of a delicate recording apparatus, the observer just mentioned has shown that from the time of appearance of rigor to the entrance of muscular putrefaction (a period of days and even weeks), there is an alternate contraction and relaxation, many times repeated, of the fibres involved. It is suggested by Brown-Séquard that the chemical changes which pave the way for putrefaction are the efficient stimuli of the contractions, which in some instances were measured, and were found to consist in a shortening of the muscle to less than two-thirds of its length in the relaxed state.

With the suggestion that daily microphonic observations of the muscles after death would probably throw decided light upon the subject, we must await with great interest the further data of a discovery, which, if confirmed, disproves the coagulation theory of rigor, and which most surprisingly postpones the period of actual death in one of the most important tissues of the body.

MUSCLE AND TENDON REACTIONS.

The interesting observations of Drs. S. Weir Mitchell and J. Morris Lewis, concluded in this number of The News, on certain tendon and muscle phenomena, are not only of value as positive addi-

tions to our physiological knowledge, but they seem also to contain the promise of a deeper insight than we yet possess into the laws governing muscular irritability in normal and pathological states. In a subject so well threshed out as this has been since Westphal's discovery, we could scarcely have expected to find so many novel points.

The authors agree with previous observers, that the knee-jerk, and other responses to tendon taps, are direct muscle acts, and a very considerable portion of the research consisted in a study of the various circumstances which increase or lessen these acts. The influence of volitional acts, already noted by Jendrássik, and the effects of strong galvanization of the brain in increasing the knee jerk, are truly remarkable, while a combination seems capable of inducing in healthy individuals a sensitiveness of muscle such as is only met with in disease.

The passive tension, upon which Gowers and others lay such stress, is not thought to be essential, and they support their position by several striking observations. The tone and intrinsic irritability suffice, and by virtue of these, and not the passive tension, though this may assist, the muscles respond to various excitations. The study of the direct muscle reactions is very interesting, particularly in the relation established between them and the so called reflexes. It seems odd, as the authors remark, that the electrical contractions of muscles are not reinforced by means which add to the knee-jerk and muscle reactions. We should certainly have expected a similar result.

The overflow theory which the authors adopt to explain the increase of the knee-jerk by voluntary acts, etc., seems to meet the case, but it is of secondary consideration in comparison with the value and suggestiveness of the facts worked out in this important research.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, February 2, 1886.

The Vice-President, Leonard Weber, M.D., in the Chair.

Dr. C. L. Dana reported a case of

TOTAL TRIGEMINAL PARALYSIS WITH ALTERNATE HEMIPLEGIA, AND THE RELATION OF THIS PARALYSIS TO THE SENSE OF TASTE.

The patient was a single man, aged thirty-five, under the treatment of Dr. George L. Fox, for eczema of the scalp. He had always been healthy, and gave no history of syphilis or excessive indulgence of any kind except in athletic sports. In August, 1885, he was attacked with a trigeminal paralysis on the left side, affecting all of the sensory branches of the fifth cranial nerve, and to some extent probably the motor branch. The paralysis came on without any other complicating symptoms. In December, 1885, he was attacked with a crossed hemiplegia, affecting the right arm and leg, and the right side of the face. When seen by Dr. Dana in consultation, the paralysis was found to be not very complete, that of the face especially not being very marked. There were no sensory and only very temporary speech disturbances. There was complete anæsthesia in the distribution of the left trigeminus, but no loss of taste on either side of the tongue. The patient soon recovered in a considerable measure from his crossed hemiplegia, but the sensory paralysis remained unchanged. In Jan. 1886, the patient had an attack of left hemiplegia.

Dr. Dana discussed the question of the nerve of taste, and referred to the contradictory opinions at present held regarding it. Most authorities now believe that the glossopharyngeal gives power of gustation to the posterior third of the tongue, and that the fifth nerve similarly supplies the anterior two-thirds, sending fibres to it via Meckel's ganglion, the great superior petrosal, the seventh nerve, and the chorda tympani. Gowers has recently declared that the sense of taste is supplied by the fifth alone. The speaker presented a review of all the evidence so far collected, and came to the conclusion that the glossopharyngeal is probably the sole nerve of taste. In his own case the lesion was probably a small hemorrhage in the lower part of the pons.

Dr. Samuel Sexton said that ten years ago it was considered proper to divide the chorda tympani for tinnitus aurium, and it was supposed to have been done. This nerve has a long and circuitous course through the tympanic cavity, and is surrounded by a sheath of mucous membrane liable to inflammation in the acute purulent processes of the ear, especially in children. He had seen and studied a large number of cases in which, owing to acute purulent inflammations, there was complete destruction of the tympanic contents, including the chorda tympani; there was no alteration of the sense of taste, though the tests to discover such an alteration were carefully made. An Italian writer has called attention to the chorda tympani as a nerve in intimate connection with speech; that certain word sounds could not be found when it was absent. But Dr. Sexton's experience had not verified this. Taste is a complex function which is developed slowly by cultivation. When the tympanic membrane is absent, so that a probe can touch the inner wall of the tympanum, a variety of reflexes can be evoked, such as vomiting, coughing, sneezing; secretions, especially in the region of the tonsils and pharynx, are increased, as is also the saliva.

Dr. M. A. Starr reported ten cases of total anæsthesia following neuralgia of the trigeminus in which there was no loss of taste. In his study of the lesions of the medulla and pons there was no record of loss of taste, though all of the cranial nerves, except the ninth and tenth, were involved; all of which would support the views advanced by the author of the paper.

Dr. A. D. Rockwell had seen many cases, and instanced one in which there was neuralgia of the seventh and fifth pairs of nerves, accompanied with loss of taste.

Dr. Dana, in closing the discussion, thought the cases cited by Dr. Sexton showed that the chorda tympani does not carry the nerve-fibres of taste at all; that they were proof that they must take another course from that described by most of the text-books. It hardly

seems probable that they have so complicated an arrangement as that claimed by Gowers, which he showed by means of a diagram.

VASOMOTOR NEUROSES.

DR. M. ALLEN STARR said that under this title he included a series of disturbances of circulation and nutrition, the causation of which could be traced to disorders of the nervous system. He selected this subject because it was one which had been somewhat neglected in the discussions of this Society, because no definite summary of the present state of knowledge of the physiology of the vasomotor action had lately been presented, and because he had recently seen a number of cases which might be classed together under this title, and which he wished to have discussed by the members present.

Disturbances of the circulation may occur in any part of the body, and are to be regarded, not as distinct diseases of the parts in which they occur, but as symptoms of lesions of the peripheral, or sympathetic, or central nervous systems. At the present time, however, it is impossible to make a pathological classification of these symptoms, and therefore they may be discussed together. In treating of the subject of vasomotor neuroses, the physiology and pathology of the vasomotor system can be discussed together with advantage.

Since changes in the force and frequency of the heart's action and variations in the total amount of the blood in the body affect the body as a whole, the state of the circulation in any one organ or part depends largely upon the degree of contraction or dilatation of its vessels. This is known as the local vascular tone. It is under the control of the system of nerve ganglia with their subservient fibres, which are found in the smaller arteries. The energy expended by these ganglia is manifested by a constant contraction of the circular muscular coat of the artery, a contraction which is constantly opposed by the dilating force exercised by the blood-pressure within the vessel. In a state of health an exact equipoise between these forces never occurs. Variations, however, in the vascular tone are produced either by local influence, or by influences reaching the ganglia from a distance through the vasoconstrictor or vasodilator fibres. The constant manifestation of energy in the maintenance of arterial tone does not have its only source in the local ganglia, but is derived partly from the central nervous system through the vasoconstrictor nerves. Here the experiments of Claude Bernard were detailed. From these experiments, it was concluded that a dilatation of the vessels follows: 1, a paralysis of the local ganglia in their walls; 2, separation of these from the sympathetic ganglia; 3, a destruction of the sympathetic ganglia; 4, a separation of these from the spinal cord by division of the anterior spinal nerve-roots; 5, a disintegration of the cord; 6, a separation of these centres from the medulla; 7, the destruction of the medulla oblongata.

The action, so far considered, has been wholly of a vasoconstrictor kind, and the dilatation mentioned has been due to a suspension of constrictor energy, normally passing outward. This is a passive dilatation. But further experiments have shown that another kind of dilatation may be produced, due to an impulse of an active kind sent to the local ganglia by the vasodilators. This is an inhibitory impulse, arresting the constrictor action of the ganglia in the vessel walls, in spite of the continued energy sent them from the central nervous system by the constrictors. Here the experiments on vasomotor dilatation were given, and the various theories of the mechanism of dilatation in the vessel walls, it being concluded that there was no mechanism in the wall which could produce a dilatation, and that a dilatation was due wholly to the blood-pressure within overcoming constrictor action.

The subject of vasomotor reflexes was then taken up, and it was shown that the seat of these reflexes is in the dorsal region of the spinal cord, since all vasoconstrictors and vasodilators can be traced to that region. The particular area of the spinal cord governing these reflexes, was thought to be the gray matter surrounding the central canal, and including the fascicular columns of Clarke. As bearing on this point, the author referred to the observations by Jacubovski, Schultze, and Fürstner. It is impossible to say from these cases whether vasomotor functions are located in the column of Clarke or in the gray matter around the central canal, or in both.

Vascular tone of the thoracic and abdominal organs is regulated by centres in the pons and medulla. Experiments of Bernard were related, and cases of diabetes mellitus and diabetes insipidus produced by lesions of the medulla and pons were mentioned. The influence of the vasomotors in the production of functional disorders of the stomach and intestines was alluded to.

From this review of physiological experiments and pathological facts, it becomes evident that the disturbances of vascular tone, which are included under the title vasomotor neuroses, may be produced by many different causes acting upon many different organs. The author here mentioned a number of possible causes and their location, after which he gave the histories of seven cases of vasomotor neuroses with remarks on the same. These cases seemed to illustrate some of the conditions which have still to be classed under the term vasomotor neuroses, from want of a more perfect knowledge of their nature. They appear to be little noticed in the books, and rarely discussed in societies; but they certainly merit careful study, inasmuch as they require cautious and scientific treatment.

DR. SACHS thought that some statements made by Dr. Starr elucidate some obscure points in experiments which he made several years ago on animals, to discover the relation of the spinal cord to the secretion of the kidneys. Eckhardt had stated that section of the cervical spinal cord had the same effect as section of the medulla; that is, to inhibit the secretion. These experiments were difficult, because of the necessity of keeping up artificial respiration, but they showed that urine was secreted as in health, though somewhat diminished in quantity. That it was actually secreted, was proved by introducing chemical substances into the blood, the coloring matter of which was shown in the urine secreted. The results obtained by Eckhardt were probably due to peripheral irritation caused by laying bare the ureters, which interfered with the secretion of the kidneys. He asked Dr. Starr what views he advanced with reference to the course of the vasoconstrictor nerves.

DR. STARR replied that one theory is that they pass from the lateral tracts of the cord through the fourth, fifth, and sixth cervical, into the sympathetic system, and thence to the viscera. Another is that they enter the sympathetic as far down as the level of the first dorsal. There is an intimate connection with the kidney. Experiments high up in the cord would, of course, produce diabetes.

DR. SACHS said that in his experiments high up in cord there was no diabetes.

DR. C. L. DANA considered himself indebted to Dr. Starr for so able a paper. The local vasomotor ganglia had been assumed to exist, but had never been satisfactorily demonstrated as physiological entities. Vasomotor disturbances are common as symptoms, and are so considered rather than as a distinct disease. Accompanying them there are almost always marked sensory and trophic symptoms, especially if chronic and had made an effect on the system. In this class of cases are those vasomotor troubles of the extremities, such as digiti mortui, and mild types of renal disease; flushing of the ears, Basedow's disease, and diabetes, should also be ranked among these. It gives rise to confusion to consider the vasomotor system as independent, in the same way as the sympathetic system, forgetful of the relation of both of these to the cerebro-spinal.

DR. WEBER spoke of the connection of sciatica with diabetes. While sugar is found in the urine of patients suffering from protracted sciatica, there were few cases of well-developed diabetes in which there was sciatica. He related three cases of sciatica in which there had been sugar in the urine, and the attending symptoms of diabetes. He had seen cases where sugar was present *after* sciatica; but he was doubtful if cases of true diabetes were developed by sciatica.

DR. LESZYNSKY related two interesting cases of vasomotor disturbances. He questioned whether cold is not a factor to be considered, since a case of symmetrical gangrene under his observation had relapses on cold days. Chilblains are common in winter.

DR. STARR, in closing the discussion, remarked that the vasomotor local ganglia had been very recently demonstrated by French physiologists in frogs, rabbits, and cats. He did not intend to give the impression that sciatica caused glycosuria, but referred to those cases, quite a number of which were on record, where there was a sudden appearance of sugar in the urine which afterward disappeared.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, February 1, 1886.

THE PRESIDENT, SAMUEL NICKLES, M.D., IN THE CHAIR.

DR. PHILIP ZENNER, in introducing the subject

TUMORS OF THE BRAIN,

remarked that our present knowledge of cerebral localizations lends especial interest to the subject of cerebral lesions. This knowledge is, however, of least practical value in its application to neoplasms of the brain. This is the more to be regretted because of the probability that brain tumors will be soon relegated, in part at least, to the domain of surgery. This inability to locate neoplasms is made more serious, and our operative treatment is made less hopeful, by the fact that a large tumor, or even multiple tumors, may remain, at least for a long time, latent, while a small tumor may produce symptoms; again, a small tumor of the brain may produce marked symptoms, while a large tumor in the same locality produces none; in other words, tumors in the same locality differ greatly in the symptoms they produce.

The features of a brain tumor which produce symptoms are: 1, its location; 2, its size; 3, character, density, vascularity, etc.; 4, the rapidity and manner of its growth; and 5, the extent to which it destroys or softens the brain substance. These various factors bear a certain relation to the kind of tumor. For instance, cysticerci are of soft consistence, and do not destroy the brain-substance; carcinomata and like hard tumors destroy the nervous tissues; so it may prove that certain tumors have their characteristic symptoms. But it is not now possible to make such an assertion.

Brain tumors produce symptoms in two ways: First, by causing general increase of the pressure within the cranial cavity; and, second, by the direct influence which they exert on the brain tissue in their immediate neighborhood. Tumors of the brain may destroy the nerve tissue; they may cause softening, or they may produce compression of the tissues in their locality. To produce local compression of the nervous tissues the growth must be harder than the tissue in which it lies. If it is softer, while it may produce heightened intracranial pressure, local symptoms are not produced. Thus, soft tumors of certain parts of the brain, as of the pons, have been found of a size which greatly increased its size, and yet in which no symptoms were produced which were referable to the pons. If a tumor be located in the cortical portion, the brain may gradually accommodate itself to the increasing pressure, and no symptoms will be produced; but in the base, direct pressure produces symptoms. Another reason for the production of symptoms in tumors of the base of the brain is the presence in that locality of large nerve-trunks, so that a very small area at the base corresponds to a very large one at the cortex. Furthermore, it appears that when a part of the cortex has been destroyed, another part may take on its function. The symptoms produced by these changes are either those arising from a loss of function or from irritation. It produces irritation when it is subject to constant changes in size, as when it is vascular in character, or when it causes inflammatory changes by its continued growth. Another mode is by the increase of intracranial pressure depending on the size of the tumor and the rapidity of its growth. There is increase of pressure in every part of the cranial cavity, but the increase in all parts is not precisely equal. The increase of intracranial pressure may thus produce symptoms which are ordinarily of local significance. Thus, the olfactory nerves may be compressed between the brain and the frontal bones. Loss of smell occurs independently of the locality of the tumor; and the third, sixth, or seventh nerve may be affected in the same way. The nerves may be compressed where they pass through the tense dura mater, or they may be compressed by the enlarged bloodvessels.

Such conditions are liable to be sources of error in

the localization of brain tumors. It is well, therefore, to remember this rule, that focal or localizing symptoms are the less valuable in making a local diagnosis the more marked are the symptoms of heightened intracranial pressure.

The most characteristic symptoms of heightened intracranial pressure are, headache, double optic neuritis, vomiting, changes in the pulse and in the mental condition. Headache is the most prominent, and is often of great severity, almost driving the patient wild. If the pain be quite circumscribed and be constantly in one place, it is likely to point to the seat of the tumor; this is especially true if there be tenderness over the circumscribed part. Usually, however, pain is of no value in localizing the tumor. There is one exception to this statement, however, that is of importance, and that is that a constant pain in the posterior part of the head and neck localizes the tumor, as a rule, in the posterior fossa of the skull. It is occasionally found that the headache and pain disappear when paralytic symptoms develop; probably this is because a part of the brain tissue has been destroyed and the pressure has been relieved. There are other cases in which pain is never manifest; these are chiefly tumors of very slow growth.

Convulsions may occur in tumors of any part of the brain. These convulsions can sometimes with difficulty be distinguished from epilepsy; they are often quite limited, however. Double optic neuritis is a common general symptom, and is believed the most nearly pathognomonic of brain tumors. It often is not noticeable unless specially sought for. It not infrequently affects the vision of one eye more than that of the other; but sometimes it causes total blindness. Blindness setting in early is of value in localizing the tumor. Vomiting indicates a tumor, in that it occurs independently of the condition of the stomach, whether that viscus be full or empty, and is often precipitate in character.

The chief localizing symptoms of brain tumor are, paralysis of the cranial nerves, hemiplegia, hemianæsthesia, monoplegia, partial spasms, reeling gait, aphasia, and hemiopia. Some of these symptoms may also be caused by the increased intracranial pressure regardless of the localization of the tumor. It may also be mentioned that in some parts of the brain tumors are latent. This is especially true of parts of the frontal lobes, the corpora striata, and optic thalami.

The diagnosis of the existence of brain tumors is based upon the presence of general symptoms, or upon the presence of gradually increasing focal symptoms. When an individual suffers from a constant headache that is not relieved by ordinary methods of treatment, he should be examined for a brain tumor. If, then, a double optic neuritis is discovered, it is an almost indubitable symptom of brain tumor.

Of the medical treatment of brain tumors I shall say little. Apart from opium as a narcotic, the iodide of potassium is the best drug. Given persistently in large doses, it is said to have produced cure in cases which were not of syphilitic nature. It is probable, however, that in the near future operative procedures will be employed, at least in a number of cases. An operation for brain tumor will be thought of chiefly in connection with lesions of the convexity.

Let us consider briefly what symptoms point us to a proper diagnosis. Tumors of the skull, which appear externally, need no special mention. Headache is an important localizing symptom. When it remains constantly in a circumscribed part, especially if pain be produced by percussing the head at the same part, it points to the probable seat of the tumor; certain motor symptoms are of great value. Monoplegia—that is, a paralysis of one part of the body—if of central origin, is usually due to lesion of the cortex. Clonic spasms, especially when confined to one part, as to one side of the face, and in cases of more general spasm, the symptom is generally indicative of the presence of a tumor. But the symptoms do not always point to lesions of the cortex. When a monospasm occurs in a part previously paralyzed, a doubt can scarcely be entertained that the lesion is in the cortical portion, and that this lesion is a tumor. Hemiopia and aphasia are usually due to cortical lesion. Such are the symptoms which under very favorable auspices may point us to the diagnosis of tumors in the convexity; but we must not forget that the value of symptoms are in the inverse relation to the indications of increased intracranial pressure. In the foregoing we have had in view the removal of a tumor which could be thought of only when it occurs in an accessible part of the brain.

Wernicke has suggested another operative procedure in cases in which removal is not to be thought of—that is, tapping the ventricles in order to relieve the intracranial pressure. In some cases the increase of pressure is not sufficient to warrant this procedure, but in many cases it is considerable. Tumors in the posterior fossa of the skull usually cause a large accumulation of fluid in the ventricles.

One symptom is so common and so important in such cases that it must be spoken of at length. This symptom is blindness. The distended third ventricle presses downward on the optic chiasm and produces atrophy. These are the cases in which blindness appears early. Double optic neuritis rarely produces blindness, but when this occurs in this connection it is usually the result of complications, generally an atrophy of the nerve. This atrophy of the nerve is usually the result of a tumor in the posterior fossa of the skull, generally of the cerebellum. Therefore, blindness occurring early is of much importance, not only in a diagnostic sense, but also because, if tapping prove beneficial, it indicates the urgent necessity for immediate treatment.

In concluding his remarks, the speaker reported several cases of brain tumor which had come under his observation, in connection with which he made further remarks on the tapping of the ventricles.

Dr. James T. Whittaker remarked that although he had come with the intention of listening to the specialist, and not of speaking, he would venture to give the views of a general practitioner. Brain tumors, if he might judge from his own experience, are rare. From an experience of twenty years, he thought he could say that he had not seen enough to average more than one case each year. He had seen more cases of sclerosis than of any kind of brain tumor. Being rare, they have more of a scientific than a practical interest; and as the most interesting question connected with the scientific consideration of the subject refers to the cause of these growths, he had hoped to hear a fuller consideration of their causation this evening. This is all the

more interesting to us now, since the advance of the theory of Cohnheim, that all tumors are developed from embryonic tissue, and it would be interesting to know just what relation this kind of tissue bears to brain tumors.

Brain tumors frequently are the local expressions of a general condition. They are generally syphilitic, tubercular, carcinomatous, or sarcomatous, and we, therefore, have in the age of the patient alone an important indication of the character of the growth—tuberculosis in early life, syphilis in middle life, and carcinoma in later life; sarcoma being the carcinoma of youth. The speaker thought that he had made better hits in the diagnostication of brain tumors by judging from the age of the patient and the presence of some disease in another part of the body, than from any other feature of the case. Even a syphilitic tumor may usually be diagnosticated from the existence of some trace of the disease long after its more active manifestations have disappeared. Tuberculosis seldom occurs in the brain, except as basilar meningitis, without some manifestation of the disease elsewhere. So with carcinoma; it is rare to find it in the brain without its presence in some of the more frequent localities of its invasion. Dr. Zenner has given an admirable exposition of the symptomatology; and it is surprising to know how many new points have been added to the knowledge of this subject in the course of a year. The diagnosis of brain tumors has been repeatedly studied, and offers us now little difficulty, and the character of the growth does not offer much difficulty as a rule, but the point which is of most interest, the localization of the tumor, is still invested with great difficulty. Dr. Zenner has put in the foreground certain symptoms upon which especially we base the diagnosis of brain tumor. Chief among these is the character of the pain, and stress has been laid on the persistence of pain. A patient with persistent pain in the head, associated with some paretic manifestation, whether with difficulty of vision or not, and whether he denies or affirms the existence of trouble in his eyes, we send to an oculist. A choked disk in connection with these symptoms means nearly always tumor of the brain. The speaker had never yet failed to make a correct diagnosis of the character of a brain tumor where a choked disk was found in connection with headache and paralysis or paresis. The location or character of the pain, in his experience, localized the tumor rather as an exception and not as a rule. Once, where he had thought to localize a tumor in the anterior fossa of the skull, from the constant localized supra-orbital pain and tenderness, and where he had been later compelled to admit the existence of lesion in the posterior part, in the cerebellum, on account of the reeling gait, the post-mortem showed the presence of a tumor nowhere else than in the cerebellum.

The localization of brain tumors has, of course, its practical side as well as its scientific side; but the fact that a brain tumor has been cut out, although a brilliant triumph of diagnosis, would give him less hope than a pylorectomy, because, as the speaker of the evening had said, the operation would be practicable only in those cases in which the tumor is located in the convexity. Of the tumors which have come under my observation, all have been localized deeper in the brain substance, and in the cerebellum for the most part. Since, then, only a few tumors are situated in the cortical region, but very little hope could be afforded by an operation. The probability is that a carcinomatous tumor would return; that a tubercular tumor would be multiple; a syphilitic tumor would not require extirpation; and so we would have to confine ourselves to the sarcoma or glioma, and the glioma distinguishes itself by not being circumscribed. It shades off gradually into healthy brain substance, a large portion of which would have to be removed. Successful extirpation of tumors of the brain would not, therefore, offer even as much hope as extirpation of tumors of the pylorus. The case would be quite different if we could attack the tumor with the galvanocautery wire or needle, without exposing it; without removing a large amount of brain matter before the tumor is reached. In many cases in which the speaker had witnessed the removal of these growths upon the post-mortem table, a large amount of healthy brain substance had to be removed, as stated, in order to get at the tumor. Then, too, other tumors are firmly adherent to the brain; they are not encapsulated, so as to be peeled out like an orange.

He would not like to be understood as saying that brain tumors can be diagnosticated by the general condition of the patient, by the presence or absence, for instance, of syphilis, tuberculosis, or cancer elsewhere in the body. The truth is, brain tumors develop for the most part in individuals previously apparently healthy, and, with the exception of a few cases which follow traumata, seemingly without cause. But the recognition of a brain tumor calls for a search for these various diseases in recognition of its character. The speaker thinks that the choked disk is accounted for by the expression of the cerebral fluid between the sheaths of the optic nerve out to the retina. He is certain that this condition occurs very frequently without blindness, or without any marked disturbance of vision. Hence, it is in his opinion a much more valuable symptom than visual disturbance.

Dr. C. W. Tangeman took exception to the views of the last speaker with reference to the possibility of locating brain tumors from the presence of a choked disk. He did not think the ophthalmoscope possessed as much value in the localization of intracranial diseases as is sometimes claimed. The exact method in which the double optic neuritis is produced is not fully understood. Von Gräfe has suggested the possibility of its being due to increased intracranial pressure, and several other views have been expressed by other authors since his publication, but not one of them is satisfactory. It has been shown that we may have a tumor of the brain the size of one's fist, greatly increasing the intracranial pressure, without any optic neuritis whatever. Cases are on record in which brain tumors have existed for nine years without producing any effect on the optic tract. Cases of total blindness have been reported following a tumor the size of a cherry, where the increase of intracranial pressure could have nothing to do with the optic symptoms. So far as localizing the tumor by the effects it produces is concerned, we are frequently misled, because the intracranial pressure may produce a meningitis from which a neuritis—a descending neuritis, as it is called—may follow, and mislead us entirely. The fact that we have optic neuritis, or that we have optic atrophy, does not always indicate that the symptoms

are due to brain trouble. If we have the general symptoms of brain tumor, associated with optic neuritis, we may be more certain in our diagnosis. As regards the relation of blindness to brain tumors, the speaker thought it the rule and not the exception, as stated by Dr. Zenner.

DR. JOSEPH RANSOHOFF remarked that the disposition on the part of neurologists to turn cases of brain tumors over to surgeons is anything but acceptable to the latter. The time has not yet arrived when these tumors can be operated upon successfully. The two cases of operative interference in brain tumors which were reported in England during the last eighteen months, and which, so far as the speaker knew, are the only ones on record, do not encourage others to pursue a similar course. Were it possible, which, as Dr. Zenner has shown us, it is not, always accurately to locate the cerebral neoplasm, operative measures would be feasible in only a small proportion of cases. In removing tumors elsewhere seated than on the convex cortex, insurmountable difficulties arise in the way of the operator. It is not impossible that in the near future, when greater accuracy in locating deep-seated neoplasms has been attained, electrolysis may be resorted to for the destruction of such growths as the knife cannot reach. In cystic tumors this would be particularly likely to be followed by good results.

His experience did not agree with that of Dr. Whittaker regarding the frequency of brain tumor. It was quite certain that he saw an average of one brain tumor *per annum*. The tumors which he saw were mostly located in the cerebellum, and in all of the cases the diagnosis was satisfactorily made from the vomiting, cerebral headache, reeling gait, and optic neuritis. The reeling gait and optic neuritis are, in the speaker's experience, so constantly present in cerebral neoplasms, that when these two symptoms are prominent in any case a strong suspicion of cerebellar tumor should be entertained. When a double optic neuritis supervenes, in addition to other symptoms, there can be no doubt as to the condition.

He regretted to learn from Dr. Zenner that so many complications depending on anatomical relations should exist to render more difficult the localization of a cerebral growth. He had hitherto taught that, with a fair knowledge of the course of fibres in the brain, such localization is easy. The rocks upon which a diagnosis may "go to pieces" having been pointed out by the essayist, the speaker will in the future be more careful of the manner in which he treats of the ease with which the situation of cerebral growths can be recognized.

DR. E. G. MITCHELL expressed his surprise at the statement that the diagnosis of cerebral tumors is easy. He had always thought that these growths are, above all others, difficult of recognition. The symptoms are certainly often vague and of doubtful value. He had seen a post-mortem in only one case of brain tumor, and in that the growth had not been suspected until recognized on the post-mortem table. No symptoms whatever had been produced that indicated its presence during life, although the growth was as large as a walnut and situated in the cerebellum.

DR. ZENNER, in closing the discussion, remarked that one condition, namely, a double optic neuritis, is of more importance than any one condition that can be found in the diagnosis of brain tumor. It is said to occur in some other conditions, in certain of the acute infections, and in some kinds of chronic poisoning, etc., but it is of so frequent occurrence in tumors of the brain, as to be of the greatest importance in them. He would not hesitate a moment in the diagnosis of a case of persistent headache in which he found double optic neuritis. There are many cases, or at least some cases, no doubt, in which a brain tumor has existed for a long time without any symptoms whatever, but there are many of these same cases in which a tumor might have been discovered if it had been sought for. In more than half the cases in which it is sought it is found, but it is not always present. This symptom of a brain tumor sometimes appears and disappears. It is also sometimes accompanied by no perceptible impairment of vision. Förster finds some defect in the periphery of the field of vision in all cases in which there is double optic neuritis. We should attempt to find those symptoms which are easily recognized if suspected, but the difficulty is that we are not accustomed to look for these minute impairments of function. It is a rare thing to find double optic neuritis in itself leading to blindness, and blindness is of value in locating the tumor in the posterior part of the brain. Tumors that can be removed are rare, and it is rare that tumors of this character can be diagnosticated. Reasons have already been given why tumors at the convexity do not generally produce symptoms. With regard to the tapping of the ventricles, although there is no positive rule for its being resorted to, the speaker thought that it should be considered in all cases for the sake of palliating the symptoms. The question is whether we can prevent the occurrence of total blindness, the advance of the reeling gait, and the mental impairment, which sometimes are symptoms of the greatest importance in these cases. These patients sometimes live a long time; in one of the cases referred to by the speaker in his report, a patient had lived five years, possibly much longer, after he had become totally blind and deaf, but such prolonged existence was merely prolonged misery. If the operation would be of benefit, the patient might live all this time with his eyesight and his hearing. In another of his cases the sight and hearing have remained unimpaired for six months, and it is a question of great import whether or not these faculties can be retained.

With regard to the diagnosis of cysts, the speaker concluded that the cysticerus is more easily recognized than the echinococcus.

In answer to a question by Dr. Reamy, Dr. Zenner said that, of all the symptoms of brain tumor, double optic neuritis is the least valuable in helping to localize the growth. It throws no light whatever upon the seat of the tumor.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, January 20, 1886.

THE PRESIDENT, CHARLES MCBURNEY, M.D., IN THE CHAIR.

OSTEOTOMY FOR ANGULAR DEFORMITY OF THE HIP-JOINT.

DR. C. T. POORE presented a boy who had angular deformity of the hip-joint after long-continued disease; flexion ninety degrees, abduction forty-five degrees. In

June last, he performed a linear osteotomy just below the trochanter minor, and was able to correct the greater part of the flexion; but the abduction was difficult to correct, because the application of extension had a tendency to bring the pelvis down on the diseased side, and thus prevent the correction of the abduction, and, in order to compensate for this depression of the pelvis, the limb was crossed over the sound one. In October following he performed a second osteotomy, which left the boy in the condition seen. After the second section, an old sinus on the inner side of the hip broke out, but it was not connected with the bone, and was simply a breaking down of old cicatricial tissue. At the present time there is about eight degrees of abduction, and from twenty-five to thirty of flexion, but the boy is able to walk very well. The sections were made with an osteotome.

EXCISION OF THE SUPERIOR MAXILLA FOR CANCER.

DR. L. A. STIMSON presented a patient, forty-five years old, who was admitted to Bellevue Hospital, December 9th, with the history of the appearance four months previously of a small, painless swelling on the right side of the roof of the mouth adjoining the molar teeth. Shortly afterward, he noticed that the cheek adjoining the right nostril was prominent. Both enlargements have slowly increased, and two weeks before admission there was profuse epistaxis from the right nostril, repeated at intervals for several days. The tumor in the mouth was small, but slightly elevated, not fluctuating; that of the cheek was firm and uniform; it raised the nostril and extended alongside the nose, but to only a short distance outward or upward on the cheek.

The superior maxilla, exclusive of the orbital plate and the malar process, was removed through the incision under the eye and along the side of the nose, and the tumor was found to occupy entirely the cavity of the antrum, but was not adherent to the upper posterior or lateral wall. Recovery from the operation was uneventful.

A noticeable feature in the cas s that the bone was involved only on the oor of the antrum and at its lower anterior and inner portion; that the tumor had spread downward and forward by invasion of the bone where it is comparatively thick, rather than in the more common direction, forward into the cheek at a higher point, where the wall of the antrum is thin.

CHOPART'S AMPUTATION.

DR. STIMSON presented a patient with the following history:

M. Q., thirty-two years of age, a laborer, was admitted to Bellevue Hospital, June 25, 1885. He said that in August, 1883, a heavy log of mahogany fell across his foot, crushing it badly, and producing a compound fracture of the tibia. When admitted there was fibrous ankylosis at the ankle-joint, and the patient walked on the ball of his foot, where an ulcer soon formed which was very troublesome. In 1884 the ulcer was treated in Bellevue Hospital, where he remained seven weeks, and then left with the ulcer healed. On admission in 1885 there was an ulcerating surface on the ball of the left foot through which bone could be felt. The surrounding tissues were very red and greatly swollen. On September 15, 1885, the patient was etherized and an unsuccessful attempt was made to break up the adhesions in the joint. On October 19th, Chopart's amputation was performed under antiseptic precautions. The highest temperature reached after the operation was 100.6° F. The wound healed throughout without suppuration.

On November 18th the dressings were removed, and the patient was allowed to go about. The patient now has a useful stump, and the scar is well above and in front, out of the way of pressure, and he walks squarely upon the heel. Dr. Stimson stitched the anterior tendons down, notwithstanding the fact that the joint was so stiff that it was believed to be impossible for it to allow the heel to turn up.

THE PRESIDENT asked, with regard to the second case, whether Dr. Stimson made any special effort to cut the anterior tendons long.

DR. STIMSON replied that he did not take any special precautions because of the stiffness of the ankle-joint.

PATELLA SUTURED WITH CATGUT.

DR. L. A. STIMSON presented a patella which illustrated the fact that catgut is strong enough to hold fragments of fractured patella in position for a sufficient length of time to allow of their complete union. In the course of an operation for extirpation of the knee-joint, he had occasion to divide the patella, which was united with catgut. The wound was closed, and union took place without suppuration. The operation was performed August 28, and in the subsequent December he excised the knee-joint, because of the continuation of the disease, and removed the patella presented, which had been divided longitudinally, so that the character of the union might be distinctly seen. He thought it was practically impossible to recognize the line of division. He was unable to say whether he used two or only one catgut suture. There was nothing in the specimen which answered that question, and, unfortunately, that point was not noted in the history of the case.

CLINICAL SOCIETY OF MARYLAND.

Stated Meeting, January 8, 1886.

DR. FRANK WEST reported a case of

SUCCESSFUL LAPAROTOMY FOR INTESTINAL OBSTRUCTION.

DR. RANDOLPH WINSLOW also reported a case of

INTESTINAL OBSTRUCTION SUCCESSFULLY TREATED BY LAPAROTOMY,

which will appear in full in the next number of *The American Journal of the Medical Sciences.*

The two cases were discussed together.

DR. L. MCLANE TIFFANY thought the Society should congratulate itself on having two such successful operations reported on the same night by two of its members. These are, so far as he is aware, the first recoveries from this operation in this part of the country.

DR. W. T. COUNCILMAN readily appreciated the difficulties that a surgeon encounters in doing this operation. It frequently becomes necessary for him, even in making autopsies on patients who have died as a result of intestinal obstruction, to remove the contents of the abdominal cavity *en masse*, before the exact point and nature of the obstruction can be made out.

Dr. J. Edwin Michael said it was the appreciation of just such difficulties as referred to by Dr. Councilman, that caused in Winslow's case the opening of the inguinal canal. It was impossible to say that the irreducible tumor in the groin played no part in the obstruction until its condition was investigated by operation and only when it was found to contain fluid and no intestine, was the obstruction sought elsewhere. He thought the great amount of manipulation necessary in Dr. Winslow's case made it a less favorable one for recovery than Dr. West's. A comparison of the two cases was very favorable to the claims of antiseptic surgery. In the worse case of the two, strict antiseptic precautions were taken, and a rapid uneventful recovery followed; while in the other case, in which less exposure and manipulation of the intestines were required to overcome the obstruction, there was more or less trouble. He was not of the opinion that the chill that occurred on the eighth day in Dr. West's case was of septic origin.

Dr. West said that he thought Dr. Michael's criticism of his case was very correct, and that if he had the operation to do over again he would observe all antiseptic precautions.

Dr. S. T. Earle asked whether the cæcum was distended in Dr. Winslow's case.

Dr. Winslow said, in reply to Dr. Earle's question, that he felt for the cæcum, and then passed his hand over the large intestine without discovering anything abnormal, but owing to the distended condition of the small intestine, which filled all available space, that was not to be wondered at. The cæcum was, however, collapsed, as was proved subsequently after the constriction had been overcome. It is not easy by the sense of touch alone to distinguish the different portions of the intestines, a fact which is strongly emphasized by a recent English writer.

Dr. John Chambers said, in comparing the two cases reported, that he could not see that Dr. Winslow's case, performed under rigid antiseptic precautions, had any advantage over Dr. West's case, done with but little regard to the details of antiseptic surgery. He would just as readily operate without such precautions as with them.

In operating for hernia, he said, the abdominal cavity is practically opened, and up to a few years ago no one ever thought of using any special antiseptic methods in this operation. He said our most successful operators in abdominal surgery are not strict antisepticists.

Dr. W. T. Councilman asked Dr. West whether, at the time he operated, there was any existing peritonitis.

Dr. West said that when he opened the abdominal cavity the peritoneal coat of the intestines was very red. He took it to be an inflammatory condition. No lymph or serum was present.

Dr. Wm. P. Chunn knew of two cases that he thought could have been saved had laparotomy been performed. He asked why Dr. Winslow had not enlarged his abdominal incision instead of making an opening over the inguinal canal. Would it not have been easier to sew up the abdominal wound with one single set of sutures going through the whole thickness of the walls, than to make two sets, one for the peritoneum and one for the skin and muscles? He has used the single suture in five successful cases of laparotomy and has never had any pus get into the peritoneal cavity. When he sews up the wound with this single suture, it is his custom to hold a flat sponge beneath the incision to catch all escaping blood, and thus prevent its entrance into the abdominal cavity while the needle is being passed. This is impossible when Dr. Winslow's plan is adopted.

Dr. Winslow, in answer to Dr. Chunn, said that he made a small incision at first, because he hoped to be able to relieve the trouble without incurring the increased risk of a long incision. He used the form of suture employed, because it is certainly desirable to separate the peritoneal cavity from the wound, and sometimes when the skin incision fails to unite the peritoneum will hold, and thus prevent the access of germs to the peritoneal cavity. The only change he would make in the manner of closing the wound would be that instead of passing sutures entirely through the abdominal walls, as was done in this case, he would unite the peritoneum separately with continuous catgut sutures, and then pass the deep sutures through all the tissues external to the peritoneum. In this way the danger of pus passing backward into the peritoneal cavity would be remarkably diminished. He did not operate upon the supposed hernia first, and subsequently open the abdomen, because there was absolutely no evidence of strangulation; after opening the abdomen a condition of affairs was found which, in his opinion, demanded herniotomy, though it was by no means certain in the mind of the operator and of his chief assistant that they had to deal with an incarceration of the gut. When no intestine was found in the sac, he was assured that the constriction was elsewhere. Whilst an error in diagnosis to this extent was made, it did not in any way complicate the case, but, on the contrary, resulted in a cure of the sac, whatever the nature of it may have been. Dr. Chambers is in error in supposing the case of Dr. West to have been more desperate on account of the peritonitis which was present at the time of operation. In neither of the cases was there any lymph or effusion from the intestines, hence, though both were deeply congested, peritonitis had not set in in either. The statement that both cases terminated favorably, and, therefore, the rigid antiseptics of the one had no advantage over the less stringent precautions of the other, and that the good result in both was entirely independent of the use of antiseptics, is scarcely borne out by the facts. It certainly would seem that the maxim "tuto, cito ac jucunde" was as applicable here as elsewhere. It is a mistake to say that our best operators discard antiseptics. If by "our" is meant American, it is undoubtedly an error. Homans, of Boston, and Battey, of Georgia, are the most successful American operators, and they are rigid antisepticists. Keith, who is, probably, the most successful operator in the world, likewise employs antiseptics.

There has been much written of late upon the treatment of intestinal obstruction, and there is considerable diversity of opinion in regard to it. Mr. Hutchinson, one of the best practical surgeons in England, is opposed to operative treatment until all other means have failed. He advocates abdominal taxis, which consists essentially in a series of rough manipulations of the abdomen, shaking the patient, inverting him, tossing him in a blanket, etc., with large enemata, the internal use of opium and belladonna, and anæsthesia. If this does

not succeed, he waits, puts the patient on low diet, and repeats the taxis. Treves and others advocate early operation, as soon as it is clearly established that the case is one of obstruction. Illoway, of Cincinnati, advocates the use of enemata under strong pressure. The method of abdominal taxis is dangerous, and is likely to cause rupture of the bowel or loosening of an intussusception, or increase of the hernia instead of reducing it. Enemata, under strong mechanical pressure, are also dangerous. Abdominal section offers the best chances for success, if simple means fail. Sometimes the constriction is a simple band, which can be easily divided, as in a case seen by the speaker, where the band was only as thick as a few strands of horsehair, or, as reported by an English surgeon, where the vermiform appendix constricted the ileum.

Dr. Winslow, in conclusion, said that three symptoms are sufficient indication for the operation—obstinate constipation, severe intestinal pain (especially when the coils of intestine can be seen and felt through the abdominal parietes), and stercoraceous vomiting.

DR. N. G. KEIRLE had, some years since, had a patient, aged eighty-five, who had marked stercoraceous vomiting and swelling in the femoral region. He cut down upon the swelling, and found a sac with nothing in it. He suggested opening the abdomen, but as his consultant did not agree with him, the idea was abandoned. He asked whether Dr. Winslow was sure his case was not one of intussusception?

DR. WINSLOW was sure it was not.

DR. L. MCLANE TIFFANY did not think there was any peritonitis in Dr. West's case, as there was no exudation either of lymph or serum. He thought the redness of the peritoneum due to congestion. He called attention to a phenomenon that he had often observed in twenty-seven cases of strangulated hernia upon which he had operated, and of which he had notes: if vomiting prior to the operation was present, then vomiting took place during or immediately after reduction. It had occurred in both cases reported to-night. He thought it had relation to relief, and considered it a favorable prognostic sign. It may or may not be accidental; however, he considered it worthy of consideration. Where obstruction is complicated with femoral or inguinal hernia, washing out the stomach has reduced it, and vomiting after reduction may be a reversed action and not evidence of strangulation. If inverting the patient does not liberate the knuckle of intestine, he thought it better surgery to open the abdomen than to cut wildly over the veins.

He had not operated upon a single case of strangulated femoral hernia in which the patient did not complain of pain in the region of the umbilicus, and regarded this as an important point in diagnosis. A marked hyperæmia of a limited portion of the intestine often gives rise to symptoms closely simulating those of obstruction. He thinks the persistent vomiting, after reduction of a hernia, due to a localized hyperæmia and an atony of the gut at the point of constriction. Did not think Dr. West's case should be cited as one that recovered without antiseptic precautions. In his opinion, sufficient antiseptic detail was observed, and he looked upon the comparison between the two cases as not being altogether a fair one, as the conditions were far from similar. He did not think the chill on the eighth day in Dr. West's case was the result of septic poisoning, but was probably malarial.

DR. S. T. EARLE said he did not think that one should be content with finding but a single obstruction. Others should at least be sought, for a case had recently been recorded in which the patient died from a second obstruction that had existed at the time the first one was reduced.

DR. J. EDWIN MICHAEL said, in regard to the remarks made by Dr. Chambers which were opposed to the importance of antiseptics in surgery, that it is usually recognized at present by surgeons that unless you have especially adapted apartments in which to operate, it is essential to the success of the operation, and is due your patient that every precaution should be observed.

Dr. Chambers has gone far astray in saying that most of our abdominal surgeons do not use antiseptic precautions, and especially in including Keith in that category. Keith has given up the spray, but as I am credibly informed by one who has recently seen him operate, he uses the most rigid antiseptic precautions in all other respects. It is true that Tait has had wonderful success with simple cleanliness, but it must be remembered that he operates in a private hospital where every detail of cleanliness is managed with scrupulous care. He avoids the causes of septic troubles in a way not practicable in a general hospital or private house. In regard to the unfairness of a comparison of the cases referred to by the President, I have only to say that the more they are compared the more apparent is it that Dr. Winslow's presented the most unfavorable features, and in regard to the sufficiency of antiseptic precautions, I can only refer to the candid admission of Dr. West, that in his case the antiseptic preparation was very incomplete.

DR. J. W. CHAMBERS did not think statistics would show any advantage for strict antiseptic surgery.

DR. N. G. KEIRLE thinks the operation should be done early, before inflammatory softening has begun; if not, one incurs the risk of rupturing the gut during manipulation.

THE PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, January 26, 1886.

DR. JOHN H. MUSSER presented some

NOTES ON THIRTEEN CASES OF TUBERCULAR MENINGITIS.

(See page 205.)

DR. WILLIAM OSLER then read a paper on

THE STRUCTURE OF CERTAIN GLIOMATA.

He desired to call attention to the histological character of certain brain tumors which present peculiarities of structure separating them from the ordinary small-celled gliomata.

The specimens which he showed were from three cases, the features, clinical and anatomical, of which may be thus summarized:

Case I.—Girl aged sixteen, blind from third year; intelligent; head not large. Occasional convulsions and spasms of muscles of neck. Death sudden. Tumor occupied the surface of the left thalamus, and extended

into the third ventricle. There was extensive dilatation of the lateral ventricles.

Case II.—Girl aged fifteen. Jacksonian epilepsy for over fourteen years. Small firm tumor occupied the upper part of ascending convolution.

Case III.—Man aged forty. Head pain, mental disturbance, drowsiness, the chief symptoms. Tumor, the size of a lemon, occupied the left anterior lobe of brain. The physical characters of these three tumors differed considerably. In Case I. the mass on the thalamus was firm, but the portion projecting into the third ventricle was soft, grayish in color, and looked like an actively growing neoplasm. In Case II. the small tumor at the upper part of ascending frontal convolution resembled a patch of sclerosis, while in Case III. the tumor had a large central area of fibro-caseous change with a peripheral zone of actively growing grayish-red tissue.

Histologically these tumors are similar in the dense feltwork of fibres which make up the chief mass of each, the fibres varying somewhat in thickness and in closeness of arrangement. Careful observation of teased specimens shows that the fibres are, for the most part, in connection with cells, and so far the growths conform to the type of glioma. True, we do not find here the typical arrangement of small cells with delicate protoplasm and numerous fine ramifying processes which gives to many gliomata an appearance not unlike that of a small-celled sarcoma. There are gliomata, however, with larger and more irregular cells and with coarser fibres than the description in text-books would lead us to suppose, and it was more particularly to certain characters in the cells of these tumors that he wished to call attention. A study of teased, fresh specimens can alone give a clear idea of the shape, size, and relations of the cell elements.

The following varieties of cells occur in these growths:

1. The ordinary "spinnen" or spider cell, with many processes, and which may be regarded as the characteristic cell of the glioma. These present considerable variety in size; many are not larger than colorless blood-corpuscles, others double or treble the size. The smaller have more delicate processes which in sections of hardened specimens may not be apparent. Some of the larger cells look not unlike multipolar nerve cells.

2. Large, unbranched, spindle-shaped cells, with greatly elongated processes. These resemble enormous connective tissue corpuscles, and the processes may be traced until they taper to extremely fine fibrils. Others are scarcely spindle-shaped, but present flat, ribbon-like processes. Some of these cells are among the largest and most remarkable met with in tumors. In Case I. the mass in the third ventricle was composed largely of them, and isolated ones measured as much as 0.4130 of a millimetre. They present usually single large nuclei, and the protoplasm of the cell is either homogeneous or finely granular. In Case III. these forms were also very abundant, but in Case II. they were not numerous.

3. Cells which resemble closely in appearance large ganglion cells of the nerve centres. They present a dark granular protoplasm, large nuclei, and one, two, or more processes, which either run singly or finally branch. The most remarkable looking are those with a single process springing from a balloon-shaped cell. Others have a process from either end of the cell body. They are usually much larger than the spider cells.

4. In Cases I. and III. there were structures of very curious aspect, which probably may be regarded as derivatives of the large fusiform corpuscles. These were remarkably translucent, band-like fibres, tapering slightly at either end, but without nucleus or granular protoplasm. From their close resemblance in form to the spindle-shaped cells, and from the fact that these latter often present a remarkable translucency, I think we may regard these peculiar fibres as resulting from a vitreous or hyaline transformation of the large spindle cells.

These tumors conform to the variety described as neuro-glioma by Klebs, who holds that the large ganglion-like cells found as such important constituents of these growths are derived directly from the nerve cells of the gray matter, and that in the development of this variety all the elements of the nerve tissue participate. Certainly the resemblance between many of the large cells and nerve elements is very striking, but I have not been able to satisfy myself of their relation to the preëxisting tissue parts. This is, of course, extremely difficult, but in a careful study of sections taken from the advancing regions of the growths, I have not met with appearances which would lead me to suppose that the nerve cells were in process of proliferation. Klebs states that he has demonstrated by means of osmic acid and gold chloride the nature of the cells and their processes, but this has not been confirmed, and I could not determine that the cells or fibres described above behaved in a characteristic manner with these reagents. That they are probably connective tissue elements seems probable from an examination of a large number of the cells in teased preparations. Gradations and intermediate forms can be seen between cells closely resembling unipolar or bipolar nerve ganglia and the typical spider cells with innumerable processes. Gliomata of this form are not uncommon. Klebs described fourteen or fifteen, and of five cerebral tumors of the glioma type which I have met with, only two were of the small-celled variety.

DR. WHARTON SINKLER reported

A CASE OF BRAIN TUMOR.

Miss S., æt. fifty-two. Mother, maternal grandfather, great-grandfather, two maternal uncles, and two brothers died of phthisis. Paternal ancestors long-lived. No cancer. Healthy and well up to four years old. Then had a serious illness, spoken of by some as "brain fever," another person says dysentery. Seemed to recover entirely from this and was bright, well, and agreeable. Was not very intelligent, but not by any means deficient. Catamenia first appeared at eighteen years. At seventeen years friends noticed a change in her, she was irritable, cross, and peculiar about many things. This condition of things continued through the remainder of her life, all the peculiarities becoming intensified. She was a great reader and a great eater. She was fond of literary pursuits and spent a considerable amount of time in writing and painstaking composition. She never had convulsions so far as was known. At twenty-five years she was examined as to her mental condition by Dr. Wm. Kirkbride, and he decided that, although not mentally vigorous, she was not insane.

For five or six years before her death, say at forty-five years of age, she seemed to grow stouter, less inclined to work, and in walking seemed to move slowly and with difficulty. For three or four years before her death there was a drooping of the left corner of her mouth, most noticeable in smiling or speaking. This gradually increased. For eight or ten years she has had headaches.

In the summer of 1885 she was at Atlantic City and had two or three attacks of violent headache associated with unconsciousness. These lasted several days at a time. She came under my charge in September, 1885. She then showed slight left facial paralysis, but no loss of power in arm or leg of either side. She complained sometimes of pain in the head, sometimes in the shoulder or neck. Seldom seemed to have persistent pain in one place. She had an attack of unconciousness with severe headache. Screamed with pain, but could check herself, and when asked what was the matter said she had pain, but could not state exactly where it was. At times she talked incoherently and spoke of having seen persons whom I knew she had never seen. She was unwilling to leave her bed, but if she could be persuaded to get up, could walk about. Her appetite was good, but there were indigestion and constipation. No vomiting. Vision seemed good, but the eye ground was not examined. She was eccentric in her way of talking, and said many things with the evident intention of creating surprise.

At my suggestion, she was taken to a country town in the vicinity of Philadelphia and was there under the care of Dr. J. Reeve. After reaching this place she complained of pain in the right side of the head and seemed unable to walk. Would fall into a semi-unconscious condition which would last for some hours. The temperature became elevated. The facial paralysis became more marked, but although no paralysis of the limbs existed there was general muscular weakness. The patient died on October 26, 1885.

The post-mortem examination was made by Dr. H. R. Wharton. Brain and cranial cavity: upon exposing the membranes of the brain they were found markedly congested, and the dura mater was very adherent to the petrous portion of the temporal bone on the right side. Brain removed, membranes divided and turned aside. Upon left side there was no apparent lesion. On the right side some bulging of the membranes was apparent in the region of the fissure of Sylvius, and upon dissecting them off they were found very adherent to a tumor larger than an English walnut, growing from the fissure of Sylvius about the line of the fissure of Rolando. The tumor was deep red in color, stood out from the brain tissue, and was dense to the touch. There was some effusion into the ventricles.

Dr. de Schweinitz made a microscopic examination of the growth and sent me the following report:

"The small portion sent for examination was hardened first in a solution composed of Müller's fluid one part, and methylic spirit three parts, for six weeks, and then in alcohol. Sections were cut, stained with carmine, and mounted in balsam. In the periphery the growth shows a structure composed of more or less perfectly developed fibrous tissue, more interiorly the stroma of the tumor is made up of numerous, variously sized, dilated bloodvessels, sometimes empty, but for the most part filled with corpuscles. Between these are numerous small round and large spindle cells (sarcoma tissue); scattered through the growth, sometimes singly, often in groups, there are round, yellowish-white bodies, which are probably amyloid in their nature. The tumor may be properly classed as an *angio-sarcoma*."

The growth, as may be seen, is spherical in shape and springs up out of the fissure of Silvius. The points of interest in the case to me are these. First, the probable long standing of the growth. It is likely that it began at the age of eighteen years, when mental peculiarities first showed themselves. Secondly, the absence of most of the symptoms peculiar to brain tumor. There were no convulsions, no vomiting, no defects of vision, and no pain localized in one particular spot. The facial paralysis was not noticed until three or four years before death. There were many marked hysterical symptoms which masked the true nature of the disease. These, I think, are often met with in brain tumors in women.

The following report was made by the Committee appointed to inquire into the

METHODS OF SLAUGHTERING CATTLE,

and the question as to whether cattle suffer from witnessing the slaughtering of companions.

Your Committee have the honor to report that they held a meeting at the Philadelphia Abattoir, and witnessed the slaughter of a number of cattle. As the arrangement of the building and the methods employed have been fully described to the Society in the paper of Dr. Hinsdale, it does not seem necessary for your Committee again to go over this ground; and the Committee confine their report to answering the questions proposed by the Society for the Prevention of Cruelty to Animals. We find, in the first place, that, owing to the unskilfulness in the use of the hammer by the butchers, that perhaps in the majority, certainly in a very large proportion of the cases, the animal is not rendered permanently unconscious by the first blow. In a number of instances the creature, when struck, either failed to fall, or simply went down upon his knees and rose again, and had to be driven around the pen, and sometimes struck again and again before falling. Further, it is the habit of the place to strike down several bullocks one after the other, so that one or two of the animals must lie on the ground some time before the throat is cut. In very many instances the creature seems partially to recover its senses during this time, and in some cases undoubtedly becomes perfectly conscious and even gets up upon his feet. There can be no doubt, therefore, that a large amount of unnecessary suffering is produced in the killing as practised at the Philadelphia Abattoir.

A properly directed and sufficiently powerful blow undoubtedly will immediately put an end to consciousness. It is not the general idea of the method of killing which is at fault at our abattoir so much as the unskilful way in which it is performed. If the animal were driven into a narrow pen, so as to insure quiet and a perfect opportunity for a blow; and if, at the same time, the hammer were heavier than the one now used, and were only employed by a skilful person, nothing more could be desired. In our opinion, there should be one man whose sole duty it is to strike down the

animals, since only by repetition can perfect skill be acquired.

We believe that there is a certain amount of psychical suffering induced by the present method. The animals evidently have a sense of danger, although they apparently do not recognize the point from which the danger is coming. The need for the appointment of some one who shall inspect the carcasses of the slaughtered animals was very well shown by the fact that, in one of the beasts killed during our stay, the liver was full of hardened nodules of a whitish color, and many of the lymphatic glands were evidently affected with the same disease. So far as gross appearances could determine, the animal, when killed, was in the advanced stages of tubercular disease of the liver. The nodules have been referred for examination to well-known microscopists, whose report we hope to hand in accompanying our own.

After the reading of the report of the Committee, on motion it was accepted, and the Committee were requested to present the matter, on behalf of the Neurological Society, to the College of Physicians of Philadelphia.

NEWS ITEMS.

Pasteur on the Symptoms of Rabies.—A young man who was bitten two days ago by a dog immediately took it to the Veterinary School at Alfort to have it examined; but, as the animal did not appear to be affected with rabies, it was returned to the owner—a proceeding, in my opinion, rather strange, for certainly the animal should have been kept under observation at least for some days. The young man, however, being naturally anxious about himself, wrote to M. Pasteur, asking him to appoint an hour to receive him. The illustrious *savant* immediately replied by letter, and, as it is rather instructive, I give it here in its entirety: "It is useless for you to come. Every mad dog, whether it eats or not, dies from rabies in a few days; if it eats, death takes place a little more slowly, but it never exceeds eight or ten days. In the interval it manifests rabic symptoms. Confine the dog to his kennel, where he must be fed with precaution for at least twelve days. This had better be done under the supervision of a veterinary surgeon. If the dog lives after the time indicated, you may be assured that it is not mad. Meanwhile you have nothing else to care about than the wound caused by the bite. This should not be neglected. The saliva of a dog, even that of a healthy one, contains microbes foreign to the rabic virus, as those microbes might produce abscesses, and, in certain exceptional cases, septicæmia. In case the dog should go mad, come to me without delay, 45, Rue d'Ulm, at 11 A. M., where I will apply the preservative treatment for rabies."—*The Lancet*, January 23, 1886.

The Ohio State Sanitary Association will hold its Third Annual Meeting in Columbus on February 24th and 25th. The President is Prof. Edward Orton, LL.D., of Columbus, and the Secretary, Dr. R. Harvey Reed, of Mansfield.

New York Polyclinic.—The report of the Secretary at the annual meeting of the Directors and Faculty of the New York Polyclinic, held at the College building on January 28, 1886, showed an attendance upon the clinics in that institution since the opening in November 7, 1882, of 709 physicians. Of this number, 156 had taken out the general ticket which admits the holder to the lectures in all the departments taught at the school.

The ratio of attendance upon the various departments is shown in the following list of tickets sold since November, 1882, up to January 28, 1886: Gynecology, 461; Surgery, 412; Medicine, 313; Throat, Nose, and Ear, 300; Children, 273; Eye, 250; Skin, 234; Mind and Nervous System, 207; Physiological Chemistry, 73; Obstetrics, 163; Pathology (laboratory only recently opened), 15. Total, 2702. The attendance for the present session is in excess of any previous term.

British Gynecological Society.—Mr. Lawson Tait has been elected President of the British Gynecological Society.

M. Pasteur has just received from the Count de Laubespin the sum of 40,000 francs, in order that he may extend his operations for the prophylaxis of hydrophobia.

The Journal of Nervous and Mental Diseases.—Dr. Morton has terminated his connection with the *Journal of Mental and Nervous Diseases*, which will hereafter be issued monthly, under the sole editorship of Dr. B. Sachs.

A Canadian View of the Congress Outlook.—The *Canada Medical and Surgical Journal*, in an editorial in its issue of this month, says: "In our last issue we published gladly a letter from Dr. Brodie, of Detroit, whose opinions on the subject of the International Medical Congress are doubtless shared by a considerable section of the profession in America, but, in spite of his communication, we still adhere to the position taken by us in December. We then said that, to attract the workers of other countries, the Sections of the Congress must be controlled by the men most eminent in their respective departments, and we maintained that the officers so far nominated did not, with a few exceptions, rise above respectable mediocrity. In the spirit of the 'Declaration of Independence,' we agree with Dr. Brodie that the gentlemen in question are 'the peers of any member of the profession in the United States,' but the Congress is a *scientific organization*, and the executive and Sections have, heretore, been composed of the best minds of the country in which it has met. What we maintain is that many of the Sections, as at present organized, are controlled by men who, evidently, have not the confidence of the scientific workers in the United States, and are unknown abroad. At present, the prospect is that the *peers* of the men who organized the London Congress will be absent from the Washington meeting—the men who, in the United States, occupy positions in the medical world corresponding to those held by Gull, Jenner, Wilks, Erichsen, Paget, Fraser, Flower, and others who made the gathering of 1881 so brilliant. As well may we suppose that the British profession could have made that meeting the success it was without men of this stamp as that the American profession can do without the coöperation of such men as Agnew, Bigelow, Ham-

ilton, Da Costa, Pepper, Mitchell, Loomis, Bowditch, Billings, Dalton, Martin, Leidy, Lusk, Thomas, Barker, Jacobi, Wood, Bartholow, and others who remain irreconcilable. Bombast and bluster will not cover up the disagreeable truth which is quite evident to outsiders, if not to Dr. Brodie, that, unless the present executive of the Congress patch up this unseemly quarrel, the meeting of next year is doomed to failure. The recent attempts to effect a compromise do not appear to have been successful, and we can assure Dr. Brodie that, if matters remain as they are, 'the most perfect and elaborate arrangements' will avail but little to attract foreigners in the absence from the Sections of such a number of the men who have made American medicine and surgery what it is to-day. We sincerely trust that at the next meeting of the American Medical Association steps may be taken to secure the needful harmony, without which, we repeat, it would be better to abandon the Congress."

THE NEUROLOGICAL SOCIETY OF LONDON has just been formed, with Dr. Hughlings-Jackson as President, and Dr. Wilks and Sir James Crichton Browne as Vice-Presidents. It is intended to include in the programme of the Society not only neuro-physiology and pathology, but also that aspect of neurology which bears upon psychology, both normal and morbid.

NEGRO AND CAUCASIAN DEATH-RATES.—The report of the Registrar of Vital Statistics of Selma, Alabama, in some remarks appended to a very full tabular statement of the causes of death in that city for the year 1885, presents the following interesting statistics in regard to the death-rates of the two races:

White births are in excess of deaths, 32. *Deaths among colored over births, 32.* Rate of births, 3 per 1000 in favor of the whites. Rate of deaths, 13 per 1000 less for whites.

Deaths from consumption nearly four times greater among the blacks; meningitis double; pneumonia shows the same rate as the whites. Deaths from Bright's disease double in the black race that of the white; cardiac disease double; rheumatism four times as fatal in black race; diphtheria three times as fatal in whites; malarial fever, 8 deaths among the blacks to 2 whites. There was an epidemic of cerebro-spinal meningitis during the winter and spring which greatly increased the deaths during this period. The deaths and births for the year were the same. The evident disproportion between the black birth- and death-rate is due to the fact that many births are not reported. Still, the birth-rate of the blacks is nearly equal to the whites. Were the returns perfect, the ratio of births would be in favor of the blacks. According to this statement, the excess of deaths per 1000 over the births in the black race is 7.7. The excess of births in the white race over deaths is 7.9 per 1000.

MORPHINE VERSUS HANGING.—DR. F. H. GERRISH advocates the hypodermatic administration of morphine instead of hanging as a means of inflicting capital punishment, claiming as advantages for this mode of punishment the following: (1) Its certainty; (2) Its painlessness; (3) Its freedom from the chance of horrible displays; (4) The reduction of dramatic element to a minimum; (5) Its inexpensiveness.—*Physician and Surgeon*, January, 1886.

ANTHROPOLOGICAL MUSEUM.—A project has been started in Berlin to establish there an anthropological museum, which will do with regard to the races of men what zoölogical gardens do with regard to animals. In the exhibition or garden, it is intended that representatives of various races shall permanently reside; while of such races as cannot stand the cold of the climate, representatives will be brought to Germany to reside there during the summer. An ethnological museum is to be established in connection with the exhibition, which is said to have the support of several capitalists.—*Lancet*, Jan. 30, 1886.

NOISELESS COAL FIRES IN THE SICK-ROOM.—Several lecturers on nursing have recommended that the coals for sick-room fires be enclosed in small white paper bags before they are brought in. To this suggestion a recent writer adds the useful corollary, that a thick layer of fine ashes should be allowed to remain under the fireplace. Most people dislike the appearance of a dirty hearth; but easily disturbed patients much appreciate the difference between a noisy and a noiseless fire—a reason why a gas and asbestos fire in a sick-room is preferred. For sick-room purposes the coal should not be of a bituminous, gasey, or flaring kind.—*Lancet*, Jan. 30, 1886.

A NEW METHOD OF SHOWING THE ACTION OF THE AURICULO-VENTRICULAR VALVES was shown at the last session of the Berlin Physiological Society, by DR. GAD. A canula with a flat glass cover was inserted in each of the auricles of an ox heart, the cavities being illuminated by a minute electric lamp, which permitted the observation of the valves and chords, as influenced by varying pressures of water within the ventricles.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING FEBRUARY 13, 1886.

CRAWFORD, M. H., *Past Assistant Surgeon.*—Detached from the "Shenondoah" on the 8th instant to await orders.

RUSH, C. W., *Assistant Surgeon.*—Detached from the "New Hampshire" on the 15th instant, and ordered to U. S. R. S. "Franklin."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 9 TO FEBRUARY 15, 1886.

TILTON, HENRY A., *Major and Surgeon.*—(Fort Wayne, Mich.) Granted leave of absence for two months, to commence on or about March 1, 1886.—*S. O. 8, Div. Atlantic*, February 9, 1886.

SHANNON, WM. C., *Captain and Assistant Surgeon.*—Ordered for duty at Fort Warren, Mass., relieving Assistant Surgeon John M. Banister, who will return to his proper station, Fort Adams, R. I.—*S. O. 27, Dept. East*, February 6, 1886.

EDIE, GUY L., *First Lieutenant and Assistant Surgeon.*—Ordered for field duty in New Mexico with troop "K" 8th Cavalry.—*S. O. 23, Div. Missouri*, February 8, 1886.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course, not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

LAPAROTOMY IN THE TREATMENT OF PENETRATING WOUNDS AND VISCERAL INJURIES OF THE ABDOMEN.[1]

BY FREDERIC S. DENNIS, M.D.,

PROF. PRINCIPLES AND PRACTICE OF SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; ATTENDING SURGEON TO BELLEVUE, ST VINCENT, AND NINETY-NINTH STREET RECEPTION HOSPITALS, NEW YORK CITY.

WE have met this evening to discuss a most important surgical operation. It is an operation which, limited to penetrating wounds of the abdomen, no surgeon had ever performed until within a few months, and it is an operation in which surgeons of every part of the world feel a common interest. Laparotomy for penetrating wounds and visceral injuries of the abdomen is a surgical procedure about which great diversity of opinion exists. It is now a fitting time to discuss the important question of the propriety of this operation; and although the number of cases in which this heroic method of treatment has been adopted is very limited, nevertheless, the great principles upon which the operation is based are sufficiently established to enable us to discuss the subject in an enlightened and intelligent manner.

I shall, after much deliberate thought and study, array myself upon a side in opposition to the teachings of my honored friend and preceptor, the late Dr. James R. Wood. His memory is revered by all connected with this venerable hospital, and his masterly teaching has left its forcible impress upon every department of surgery. He advocated a plan of treatment in abdominal surgery which I feel bound, in the light of antiseptic surgery of the present time, to modify. It was not a characteristic of Dr. Wood to be behind his age in his work or in his teachings. He was not only abreast, but many years in advance of his times. Since his death the science of surgery has received an impulse advancing to a point from which, upon looking back, one can observe the great revolution which has taken place. One can perceive at a glance that this great reform is due to the development of a system of surgery which was inadequately understood a few years since, but which now has the almost undivided support of an entire profession.

The operation of abdominal section has only been rendered possible within the past few months in a class of injuries which before the introduction of antiseptics were mortal wounds. Experimental work upon the lower animals in laboratories, and the cultivation of bacteria in these institutions, have opened to us new fields of inquiry and of research, and by this knowledge we are enabled to save human lives where before they were lost. Experimental work which has been carried on within the last few months in other laboratories as well as in the Carnegie Laboratory, and also the researches into the life history of microörganisms, together with a study of the value and safety of the different germicides, have rendered it possible for us to perform operations which hitherto were considered impossible and without the pale of legitimate surgery.

In the memorable debate which was held in the New York Academy of Medicine, between the late Dr. J. Marion Sims and Dr. James R. Wood, the former advocated the opening of the peritoneal cavity in penetrating wounds. *Apropos* of the Garfield case, the latter surgeon offered some very cogent arguments against this procedure, and laid great stress upon the fact that opening the peritoneal cavity in a case of ovariotomy in a patient prepared for the operation was altogether a different procedure from opening the peritoneal cavity in a case of gunshot or penetrating stab wound of the abdomen, with the accompanying shock. In ovariotomy the shock comes after the operation; in gunshot or stab wound of the abdomen the shock is present before, as well as after, the operation. Antiseptic surgery has demonstrated, within a short time, the safety of opening the peritoneal cavity, and this fact alone has changed the views of surgeons upon the question of the propriety of abdominal section in penetrating wounds. It has been clearly proved over and over again by the crucial test of clinical experience that laparotomy is not attended with any additional risk, as was formerly supposed. The peritoneal cavity is invaded daily by surgeons, and no harm follows this procedure in ovariotomy. If this is true in a certain class of surgical diseases, it should also hold good, with certain limitations, in surgical injuries. I shall endeavor to prove, by referring to a number of cases in my hospital practice, that laparotomy, in penetrating wounds of the abdomen, is not attended with any great dangers under proper conditions, and that the presence of shock should never deter a surgeon from boldly opening the peritoneal cavity in a penetrating wound.

In the paper this evening I shall consider the subject of laparotomy in

I. Penetrating stab wounds;

II. Penetrating gunshot wounds;

III. Rupture of the intestine;

and at some future time I shall take up the remaining indications for abdominal section as they present themselves to the general surgeon. And now, these two patients, who are present this evening, have both received during this winter penetrating stab wounds of the abdomen. They have both recovered and they will now be discharged, cured, from St. Vincent's Hospital. I shall avail myself of these cases to venture some remarks upon the treatment

[1] Read before the New York County Medical Association, February 15, 1886.

of penetrating abdominal wounds, and shall also discuss the treatment which was adopted in many other penetrating abdominal wounds which have occurred in my hospital services during the present winter. I shall also take the liberty of referring to some cases of this character which have occurred to me during the past few years, together with some cases reported by other surgeons.

Case I.—T. H., æt. twenty-two, was admitted into St. Vincent's Hospital, November 29, 1885. Patient was stabbed with a knife in the abdomen. A large fold of intestine protruded through the wound. The fold was circular in outline and measured about twelve inches in length. The intestine was slightly caught, constricted, and deeply congested. Upon the surface of the gut there were two wounds, one of which was longitudinal and about two inches in length, and opened into the lumen of the intestine, through which fecal extravasation had taken place. The other wound involved the peritoneal and muscular coats. I introduced into the first wound, with the assistance of Prof. Bryant, a Czerny-Lembert suture of catgut. The suture passed through the peritoneal coat on one lip of the wound, and was then brought out at a point opposite, and then the peritoneal coat was involuted so as to bring these surfaces in contact, and this continuous suture closed the opening into the intestine. The second wound was then sutured. Several inches of intestine were drawn out, after enlarging the abdominal wound, in addition to the part which had already protruded, in order to ascertain if any other injury existed. As no other damage to the gut was detected, the intestine was carefully and finally irrigated with a warm solution of bichloride of mercury, and the cavity was sponged.

The remarks that I would venture to offer in regard to this case are: First. That the operation of an exploratory laparotomy was not called for in this penetrating abdominal wound, because the intestine already protruded; that the wounds in the gut were found extraperitoneal, and hence no extravasation of contents into the cavity took place; that enough of the canal could be withdrawn, by slightly enlarging the original wound, to render the diagnosis certain that no other wounds existed. Second. In my experience, those cases of stab wounds of the abdomen are more favorable in which a considerable quantity of the gut immediately protrudes from the peritoneal cavity. In these cases the diagnosis is rendered certain, the extravasation is outside of the abdomen, and the line of the treatment is clear. Third. That the concealed wound is fraught with the greatest danger to the patient and with the greatest anxiety to the surgeon.

Exploratory laparotomy, where the gut does not protrude, removes the danger to the patient and the anxieties of the surgeon. The exploratory laparotomy may either be in the median line or at the place where the wound existed. I prefer the median incision; but, in cases of doubt as to visceral injury, some surgeons recommend the enlargement of the original wound (which operation has been termed débridement), and the inspection of the cavity through this opening. If evidences of visceral injury are present, a regular laparotomy can then be performed in the median line.

I will now introduce the next patient, who also received a penetrating stab wound of the abdomen at the time of the convalescence of the first patient.

Case II.—J. J., æt. fifty-seven, admitted to St. Vincent's Hospital Dec. 20, 1885. Patient was stabbed in the abdomen. Upon admission, was in moderate shock. A stab wound was present in the umbilical region four inches above and three inches to the left of the umbilicus. A finger-shaped piece of omentum protruded through this opening. Patient complained of being very cold, and suffered pain over seat of wound. No vomiting; pulse feeble and rapid. Three hours after wound was received, patient was transferred to operating-room, and every preparation was made for laparotomy, in accordance with the description, to be given later, of the technique of the operation. The median incision was made. The peritoneum was divided between my index and middle fingers, which were used as guides, and a probe-pointed bistoury was employed in the cavity. The incision was extensive, and through this wound the contents of the abdominal cavity were examined. Hot flat antiseptic sponges, saturated in a mild bichloride solution, were used to protect the intestine during the examination. The coil of small intestine rolled entirely out of the cavity upon both sides of the wound, and the colon and stomach were turned upward and examined upon their anterior and posterior surfaces. During the exposure of the viscera they were constantly irrigated with a warm and weak solution of bichloride of mercury. The alimentary canal, beginning above at the stomach and ending below at the sigmoid flexure of the colon, was thus carefully examined, together with the mesentery and omentum. The examination occupied about half an hour, and was thorough and complete. No wound of any viscus was found, and the contents of the abdominal cavity were replaced and the peritoneum, linea alba, and the skin were separately sutured. Toward the close of the examination of the contents of the peritoneal cavity, it became necessary to stop the administration of the ether and to use hypodermics, to which the patient quickly responded. In six hours after the operation he had reacted nicely, and his condition at the close of the day was in every way satisfactory.

This patient's temperature never was higher than 99½° F. at any time following the day after the operation, and he made a most satisfactory and complete recovery. To both Dr. Kelly, the House Surgeon, and to Dr. Davin, the Senior Assistant, I feel especially indebted for the indefatigable care, good judgment, and untiring attention which they displayed, not only in the careful preparations which they made for these operations, but also for the professional watching which they gave these two remarkable patients. Every hospital surgeon realizes, sooner or later, to what extent he is indebted to his house staff for the uninterrupted success which attends his major operations.

I am aware that this procedure will expose me to criticism as regards the line of treatment pursued. It will be urged by those who oppose laparotomy in penetrating wounds of the abdomen, that this case would have recovered without the great risks involved in this operation, and hence that laparotomy was unnecessary. That the patient would have recovered without any surgical interference is undoubtedly true, judging now from the knowledge obtained by the exploration of the peritoneal cavity. It must be remembered, however, that this knowledge was not possessed before the operation. But if, on the other hand, a wound of the intestine existed, and "the let alone, do nothing, give opium practice"

had been resorted to, the patient would have died. We must judge such a case as this by the symptoms present at the time the patient is injured, and not from an opinion formed after the exploration has been made or an autopsy has been performed. There seems to be a tendency among medical men to judge a case in the light of the knowledge bestowed by a post-mortem examination. It is very easy for any surgeon to be wise after an autopsy; but we must judge a case upon the symptoms present at the time of the injury, which is the time for the surgeon to act in order to save human life.

The laparotomy in this case showed that the intestine was not wounded, and this knowledge was requisite in order to treat the patient upon accurate and scientific principles. The laparotomy here did not add an additional risk not common to all great operations, and it demonstrated that the operation can be performed in a thorough way without any more danger than attends every surgical operation of any magnitude. The laparotomy in this case illustrates, also, that even though the stab wound which calls for the operation is not a mortal one, that the operation can be done with impunity in such wounds.

The abdominal section in this case is the first exploratory laparotomy that I can find in surgery where the operation has been performed in stab wound of the abdomen without the previous knowledge of any wound within the peritoneal cavity and without the protrusion of the gut. It is, in other words, the application of the same principle to stab wounds upon which laparotomy in gunshot wounds of the abdominal cavity is performed. It is, however, the application of a principle to a class of wounds which are not as fatal as gunshot wounds. The future practice of surgery only will decide to what extent the profession will indorse the adoption of this principle in the treatment of the less fatal class of wounds, while the laparotomy, which is a common factor in both varieties of wounds, is the same in one case as in the other.

The complete recovery of this patient after the exploratory laparotomy in a penetrating stab wound of the abdomen, places upon record the fact that the operation can be, and has been, done with safety, and that, too, when the contents of the peritoneal cavity are temporarily removed.

I am not prepared to say that I should not recommend, in another case of this kind, that the original stab wound be enlarged so as to allow the surgeon to inspect the intestine and thus see if there are any evidences of perforation or injury to the viscera. If there are any evidences of visceral lesion, a laparotomy can be performed in the median line. This plan would be a little more conservative than the adoption of the one which I have already reported.

The resolution to perform an exploratory laparotomy in stab wounds as a means of diagnosis, was not made suddenly, but was the result of much study and reflection after an extended experience in the treatment of a large number of penetrating wounds.

The study of the following selected cases which occurred in my hospital experience, and which terminated fatally after the older methods of treatment had been adopted, led me to believe that there was still much to be learned in the management of these cases, and from the experience thus gained I was led to perform laparotomy in the case mentioned.

Case III.—P. B., an Italian, æt. twenty-three, admitted to St. Vincent's Hospital, February, 1883. Patient was stabbed by a stiletto in the abdomen. The wound was situated three and a half inches from the median line and five and a half inches from the umbilicus. The wound was two and a half inches in length. Through the wound a small mass of omentum protruded. The omentum was lacerated and was bleeding. In a radius of five inches from the centre of the wound there was well-marked emphysema. The patient was not profoundly in shock. The protruded omentum was ligated, the distal portion removed, and the base attached to the wound. Peritonitis quickly supervened, and death occurred in a few days from acute peritonitis due to a perforation of the gut. No laparotomy was performed; but the emphysema made the diagnosis positive of perforation of gut.

Case IV.—W. R., æt. twenty-nine, September, 1885, St. Vincent's Hospital. Patient was stabbed in abdomen. There were two wounds, one penetrating the abdomen and situated three inches to left of umbilicus and upon a level with it. A portion of omentum protruded which was about two inches square. Patient was in a condition of moderate shock. The omentum was ligated close to the skin, and after tying a small vessel and arresting all the hemorrhage, the stump was dropped into the peritoneal cavity. A single suture was all that was necessary to close abdominal wound. Patient had violent fixed pain in abdomen, and symptoms of peritonitis, sank slowly, and in forty-eight hours was dead.

Autopsy. A large quantity of yellowish fluid was found in the peritoneal cavity. Intestine glazed over with inflammatory exudation. A portion of the omentum was found between the layers of muscles. The jejunum was perforated in two places; the two openings were separated by a narrow bridge of intestine. The appearance of the wound indicated that the knife had passed through the intestine while the surfaces were in contact. Laparotomy was the only resource which could have saved the patient's life.

Case V.—L. D., Italian, admitted to Ninety-ninth St. Hospital on February 22, 1882, suffering from a stab wound of the back and front of the abdomen, both of which penetrated the abdominal cavity. The patient died without a laparotomy. The intestine was wounded, and had an abdominal section been performed at once I feel sure that a chance of recovery would have been afforded to the patient, while in the absence of the operation the wound was necessarily mortal.

Case VI.—J. McG., æt. twenty-one, admitted to St. Vincent's February, 1885. Patient was stabbed in right groin just above inguinal canal, and about two inches from symphysis pubis. Wound small and was closed, and patient walked home, refusing to remain. Next day the ambulance was summoned, and patient was readmitted. The original wound had reopened, and there was a well-defined swelling above the wound. Peritonitis developed, and patient was treated by the old method. In twenty-four hours patient died.

Autopsy. There was an internal strangulation eight inches above ileocæcal valve. Three inches of strangulated gut were gangrenous. The volvulus was produced by the sudden stab wound. Though the intestine was not injured, a laparotomy would have probably saved the life.

In connection with this interesting case, a most important question is suggested. Is a surgeon justified in performing laparotomy, as in one of my

cases already mentioned, and examining the intestines, in a case where there is no evidence of visceral injury? This case certainly is pertinent, and demonstrates that volvulus can be produced by a stab wound, the infliction of which causes sudden peristaltic action of the gut and develops a twist in the long axis of the small intestine. A laparotomy in this case would in all probability have saved the patient's life, and yet no visceral injury in the way of a perforation existed.

This case illustrates the fact that, besides actual wound of the gut, there is another condition which is just as fatal to the patient, though no wound of the gut is present. Nothnagel's elaborate experiments upon animals, a most interesting account of which may be found in the *Beiträge zur Physiologie und Pathologie des Darmes*, Berlin, 1884, illustrate the manner in which strangulation of the bowel may occur as a result of stimulation of the intestine by the faradic current through electrodes so applied as to produce contraction of the circular muscular fibres of the gut. There is no doubt that the stimulation produced by a stab wound may also cause irregular and sudden peristalsis, which may result in a twisting of the gut upon its own axis or upon the mesenterical axis. Internal strangulations, in the form of invaginations or intussusception or volvulus, are often associated with irregular and spasmodic action of the intestine. In almost every variety of internal strangulation, or intestinal obstruction, colic, characterized by irregular spasmodic peristalsis, is a prominent symptom.

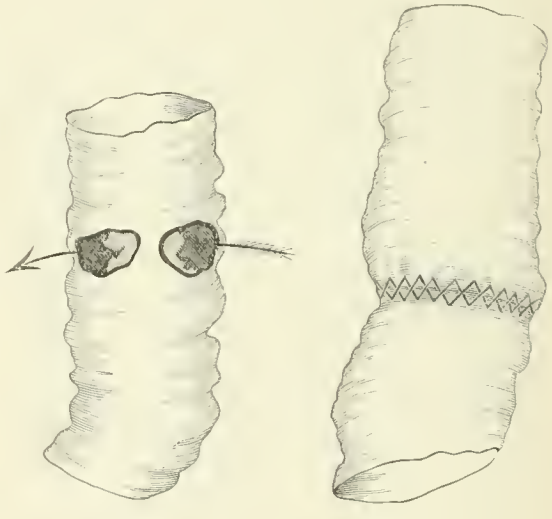
The case already mentioned clearly demonstrates that the condition of volvulus may result from a penetrating stab wound, and this condition is a most serious one, leading, sooner or later, to a fatal termination. Laparotomy will rescue a patient exposed to the dangers of internal strangulation in any of its various forms; and laparotomy for the relief of this condition in penetrating wounds is an operation which has never been suggested until the appearance of the case which I have just mentioned. I believe that this condition has caused many deaths, and that the attention of the profession should be directed to this condition, offering, as it does, a new indication for the performance of laparotomy. I can recall many other cases in my own experience which forcibly illustrate the fact that laparotomy might have saved life, and the failure to perform it in each case removed the only chance of recovery which was possible. Ten specimens, taken from the patients to whom reference has already been made, afford us a rich field for study, observation, and reflection.

Case VII.—P. B., æt. twenty-five, admitted to St. Vincent's Hospital, Oct. 1885. Patient was stabbed in the scrotum with a penknife. The knife entered the scrotum, in which there was an unreduced hernia. The incision was about an inch and a half in length. No hemorrhage from the wound. The finger was introduced into the scrotum and no intestine was felt. The subsequent history of the patient proved that the hernia had become reduced at once after the receipt of the wound. In all probability a spasmodic contraction of the intestine occurred when the gut was pierced by the knife, and this fact further illustrates the principle involved in the production of volvulus in these cases of penetrating abdominal wound. This is another case corroborative of the statement that I have made, that volvulus can be produced by this spasmodic action of the intestine as the result of stab wound.

The patient upon admission was in good condition, but the next day grew rapidly worse and soon was in collapse. An examination of the wound showed the presence of matter identical with the material which was vomited. Patient was placed under the influence of an anæsthetic by Dr. Totman, of Syracuse, and the scrotal wound enlarged and hernial sac opened. It was now evident that fecal extravasation had occurred within the abdomen, and that it had gravitated downward into the hernial sac from the pelvis. The wound was enlarged so as to explore the entire peritoneal cavity. Two large wounds of the intestine were found, and it became necessary to resect this portion in order to close the opening. The divided ends were sutured. The peritoneal cavity was cleansed with a solution of bichloride of mercury,a great amount of fecal extravasation was removed. The wound was treated as in the other cases already mentioned. The patient reacted from the operation and was in better condition after the operation than just before the laparotomy. He finally sank rapidly and died the same evening.

Examination, post-mortem, of the resected intestine showed that the wound was large and upon both sides of the gut. No leakage occurred in the line of suture when water was forced through the canal.

Fig. 1. Fig. 2.



Portion resected. Intestine sutured.

The remarks that I would offer upon this case are these: First. While the patient died some hours after the operation, in which a complete resection of a portion of irreparably damaged intestine was made, the patient survived the laparotomy, and his condition of shock was better after the resection of the intestine than previous to the operation. Second. The patient died on account of fecal extravasation into the cavity of the abdomen, and not from the direct effects of the operation itself. Third. The sutures closed completely the divided and afterward united ends of the gut, and not a drop of water leaked through the sutured portion, though the faucet was turned with full force from the Croton aqueduct.

The next specimen is from a case of penetrating stab wound of the abdomen, in which I performed laparotomy.

Case VIII.—T. C., æt. twenty-two, admitted to Bellevue Hospital January 1, 1886. Patient was suffering from a stab wound in the left side just above the centre of the crest of the ilium. Upon admission patient had a fair pulse. The wound was half an inch long, and from it there had been considerable hemorrhage. The wound was dressed aseptically by Dr. Jarvis. When I saw the patient that morning, I could find no signs or symptoms which made it evident that the intestine was perforated. The temperature was 102° F., and no shock; the pulse was 104 and of fair volume; the urine was clear; no pain except upon pressure. I passed my finger, which was thoroughly disinfected, into a large wound, which readily admitted it, obliquely forward and upward for two inches. Upon meeting with slight resistance, I withdrew the finger and gas bubbled out from the deeper parts of the wound. I thought this was evidence that the gut was perforated, and proceeded at once, with every possible preparation, to open the peritoneal cavity. The median incision was made. Upon opening the peritoneal cavity two incised and three lacerated wounds of the intestine were found. They were situated in the jejunum and ileum, and the lacerated wounds were separated by a bridge of mucous membrane. These wounds were all carefully stitched by a Czerny-Lembert suture, and the abdominal cavity was sponged out after the fecal extravasation was removed. The wound in the abdominal parietes was then closed in the manner already described. Patient rallied from the operation, and lived about forty hours, when he sank rapidly and died.

The autopsy revealed the presence of considerable quantity of bloody serous fluid in the peritoneal cavity; but no perforations had been overlooked. The wounds in the intestines were all sutured, and none of the stitches had given way in any of the wounds.

Fig. 3.

Showing gut after perforations were closed.

The remarks that I would offer in reference to this case are these: First. That laparotomy was the surgeon's only resource to save the life of the patient. Second. Notwithstanding the fact that there were five perforations, three of which were badly lacerated wounds, the sutures all held firmly, and that when the Croton water was turned on with full force not a single drop leaked through any of these various and numerous perforations. This experiment was conducted with the assistance of Dr. Jarvis, the House Surgeon, to whom I feel greatly indebted for his kind attention and skilful care of this case. Third. No perforations were overlooked in this or the following cases.

Case IX.—T. B., æt. twenty-eight, admitted to Bellevue Hospital in October, 1875. Patient was stabbed in the abdomen. The wound was situated two inches above and one inch to the right, and parallel with the linea alba. Through this opening about five feet of intestine protruded. I was unable to find any wound of the gut, and the viscera, after having been washed, were then reduced into the peritoneal cavity. The wound was sutured and the patient placed under the influence of opium. A slight amount of peritonitis developed, but the patient made a most satisfactory recovery.

Case X.—T. T., æt. fifty, admitted to Bellevue Hospital, November, 1875. Patient was stabbed in the abdomen, and many feet of intestine protruded. The viscera were washed with a warm solution of carbolic acid and thoroughly examined, and no wound being found, the intestine was returned into the peritoneal cavity. Patient was placed under the influence of opium, and after a few days recovered. This case did not belong to me, but I assisted Dr. Glass, who was then House Surgeon, to reduce the viscera. I am unable to state who was the attending surgeon at the time. This case is not included in my list.

Remarks.—These two cases, occurring about the same time, afford examples of the statement that many feet of intestine may protrude, and if uninjured may be returned, and the patient recover.

Case XI.—F. McB., æt. fifty, admitted to Bellevue Hospital, Oct. 1875. Patient was stabbed in the abdomen with a long butcher's knife. Upon admission patient was in profound shock and was bleeding profusely from the external wound, which was situated in the seventh intercostal space just below the nipple and was one inch in length. Physical examination of the chest showed no evidence of injury to the lung. Patient vomited ten ounces of blood and before admittance had also vomited blood. During the evening the patient several times vomited blood which had, it is believed, gastric juice mixed with it. Hot air bath, hypodermics of brandy and ergotine, rectal enemata of brandy and all other means were used to bring patient out of the profound collapse into which he had sunk. Patient was sustained by hypodermics of brandy every two hours, and also by enemata of milk and brandy for a period of twelve days, at the expiration of which time he was allowed to take liquid nourishment by the stomach.

These cases were admitted into Bellevue Hospital when I was house surgeon, and during Dr. Wood's time. This is a case of penetrating stab wound of the stomach, with recovery; the two preceding cases were penetrating wounds of the abdomen, with protrusion of many feet of the gut, but with no perforations in the intestine.

The following surgeons have published successful cases of penetrating stab wounds, where either a true laparotomy was performed or the original wound

was enlarged, the perforations sutured, and the cavity sponged:

Kwiencinski,	one case—recovery	1
Compton,	" " "	1
Stucky,	two cases—recoveries	2
Byrd,	one case—recovery	1
Tiling,	" " "	1
Reichenback,	" " "	1
Prieto,	" " "	1
Avery,	" " "	1
Devereaux and Hurd,	" " "	1
Glass,	" " "	1
Dennis,	four cases—recoveries	4
Total		15

There are, of course, other cases besides these fifteen, but these have been found in recent medical journals, except two cases of my own, which happened some time ago, and which I have never published; but do so now to illustrate from personal experience the statements which I have already made in this article. I have lost two cases of stab wound after laparotomy: in one, resection of the gut was made; and in the other, five intestinal wounds were sutured.

I have omitted in this summary those cases (III., IV., V., and VI.) which are reported for purposes of illustration, and which have no bearing upon the success of laparotomy, as they occurred prior to any discussion of this operation.

(*To be concluded.*)

OÖPHORECTOMY FOR THE RELIEF OF HYSTERO-EPILEPSY:

PERITONITIS WITH PERSISTENT VOMITING; CHLORAL BY ENEMA; RECOVERY.[1]

BY THADDEUS A. REAMY, M.D.,
PROFESSOR OF OBSTETRICS AND CLINICAL GYNECOLOGY IN THE MEDICAL COLLEGE OF OHIO.

MISS M. W. Y., of Kentucky, aged twenty-four, a well-developed, medium brunette, with the marked physiognomy of an epileptic, was admitted to my private hospital March 21, 1885. She began to menstruate at thirteen, and the function for one year and a half was normal and painless. Since that time, however, she has suffered greatly with dysmenorrhœa, and during the past two years her menses have been very irregular, six weeks sometimes intervening, while at other times only three and a half weeks elapsed between the periods. Menstrual coagula were seldom discharged, but at times the quantity of blood was somewhat excessive. She attributes the change in her menstrual phenomena to severe lifting.

On Nov. 10, 1883, she suffered an attack of fainting at the approach of menstruation and was unconscious for a short time. Similar attacks have occurred at each menstrual period since, and during the past year the attacks have recurred sometimes as often as five or six times per month. During some of these seizures, but not all, unconsciousness is complete, and she awakens from them without any knowledge of what has occurred. From members of her family, the information is obtained that tonic and clonic spasms of the muscles characterize the more marked attacks, but not the milder ones. From personal observation made by Dr. Hirons during seizures which occurred while she was in the hospital, it was noted that during the period of unconsciousness following an attack the respiration and pulse were but little changed, but the pupils were dilated and all the muscles were passive and relaxed except the orbicularis palpebrarum, which was somewhat contracted. At the time of her admission she complained of headache, more severe in the occipital region. She also suffered much pain in the lumbar and ovarian regions, especially in the vicinity of the right ovary.

A physical examination at the time of admission revealed no trouble with lungs, heart, liver, stomach, or spleen. Subsequent examination excluded the possibility of renal disease. The vagina was found to be normal, though somewhat relaxed from former examinations with speculum, which had been made in the course of local treatment administered before coming under my charge, and also to a pessary which she had worn. Her uterus was slightly above normal size, and somewhat retroverted. Its cervical canal was patulous and bathed in the discharge characteristic of uterine leucorrhœa; the uterine probe was admitted to a depth of two and a half inches. The left ovary could be detected somewhat enlarged, and slightly prolapsed; while the right ovary, not perceptibly enlarged, was excessively sensitive to pressure on conjoined manipulation. The Fallopian tubes could not be differentiated, nor could any abnormal condition of the broad ligaments be detected, except possibly a slight fulness on the right side near the uterus.

The pain in the ovarian region, noted above, I was informed by the patient, had been almost constant for a year, and was quite unbearable. Although apparently well nourished she was weak, easily fatigued, had poor appetite, and her muscles very flabby. She was nervous and somewhat hysterical.

Diagnosis.—Hystero-epilepsy, due to organic disease of the ovaries, the hysterical element being prominent.

Treatment.—Having obtained most satisfactory results in quite a number of cases, of a somewhat similar character, in which ovarian disease was unquestionably present, but epileptic symptoms not marked, from rest, milk diet, massage, etc., I decided to place the patient on such a course. This was done, and the treatment continued for eight weeks without improvement in any direction. During the treatment, as well as subsequently, after she had left the hospital, the bromides, cannabis indica, etc., were thoroughly tried, without relief of pain or any apparent control of the epileptiform seizures. The hydrate of chloral was given on several occasions for the relief of headache, and it uniformly aggravated the attack.

The patient was sent home in the latter part of May greatly discouraged. She visited my office at intervals of a few months until January 4, 1886, at which time she was readmitted to the hospital, for the purpose of having oöphorectomy performed. She had sought this operation long ago, but hoping

[1] Read before the Cincinnati Academy of Medicine, February 8, 1886.

to relieve her by measures less radical and revolutionary, I had constantly refused to perform it. Her pleadings were now irresistible, as her sufferings, both mental and physical, seemed beyond endurance. She had thoroughly informed herself not only of the possible dangers of the operation, but of its consequences upon her physical organization even in the event of a cure. Her family, as well as her family physician, joined in her request. The operation was performed January 18th, in the presence of Drs. Hirons, E. W. Mitchell, and my associate, Dr. Withrow.

An abdominal incision was made two inches in length. The ovaries, which with their tubes are here exhibited, were found to be hard and rather nodular, the left bearing a soft mass on its distal extremity, and the right had two or three small cysts on its surface. Each ovary with its tube was brought into view, the broad ligament transfixed, and the tube included in one side and the ovary in the other side of a Staffordshire knot. The ovaries and tubes were then cut away. A small tense cyst of the right broad ligament near the uterus was ruptured during the manipulation and its contents evacuated. The peritoneum was sponged carefully and the abdominal incision closed by four silver sutures.

The operation occupied about thirty minutes and the patient promptly rallied. The patient was ordered hot whiskey, but no solid food, during the first twenty-four hours. Six hours after the operation one-fifth grain of morphia was administered hypodermatically, as she complained of considerable pain. She slept during a portion of the night. During the second day the persistence of abdominal pain required repetitions of the hypodermatic injections of morphia three times. Vomiting occurred once. Temperature 100°, pulse 100. An ice-bag was ordered to the abdomen, and she was allowed some fragments of ice, as her thirst was considerable. On the morning of the third day very slight tympanites was noted. The pain in the lower portion of abdomen was increased. There was considerable retching and occasional vomiting. Temperature and pulse unchanged. On the evening of the third day tympanites was more marked. Pain was undiminished except when under morphia, and vomiting more frequent. Temperature 100.5°, pulse 110. Hot water was substituted for the ice, and seemed temporarily to allay the vomiting.

On the morning of the fourth day the retching was constant, and violent vomiting very frequent; the fluid ejected was dark green, so characteristic of peritonitis. Tympanites increased; abdominal pain severe, though morphine was increased. Pulse 110, and feeble; temperature 100.8°; patient very restless and anxious, and manifestly in a condition of peril. On the removal of dressings, the abdominal incision was found to be united by first intention, despite the vomiting; an enema of warm water and salt was given. During the outflow of the water from the bowel, considerable gas escaped, but scarcely any fecal matter, the rectum being empty. An enema containing fifty grains of chloral hydrate was now administered, following which she went to sleep in less than thirty minutes, and slept quietly for four or five hours. Her temperature had now fallen to 99.5°; the pulse remaining 110. She was then given some fluid nutriment, and again fell asleep, and spent the night in comfort; being free from pain, and not having vomited once since the administration of the chloral. The next day, the fifth after the operation, she complained of pain and some nausea, and was given forty grains of chloral by enema, and the symptoms vanished. On the sixth day she vomited once, and after a dose of chloral per rectum no more trouble occurred. The stitches were removed on the eighth day, when the wound had healed firmly throughout. On the right side of the incision, the lower stitch had produced some irritation, and a stitch-hole abscess formed. Her recovery has been uninterrupted; she sleeps perfectly, appetite good, pulse and temperature normal.

I shall say but little in the way of justification of oöphorectomy for epilepsy in such cases. The reports of Tait, Keith, Hegar, Thomas, Battey, Taber Johnson, Sutton, Goodell and others, are certainly quite encouraging. But the operation must be subjected to further trial, in properly selected cases, before its full value can be considered as defined. Neither do I propose, in this report, to discuss the general question of oöphorectomy for organic disease of the ovaries, where epilepsy is not present. It has been my good fortune to secure satisfactory results in such a large number of cases of ovarian disease, occurring in young subjects, by rest and other appropriate treatment, that I have hitherto been, and am now, quite conservative in the management of such cases, avoiding surgical interference until other methods have been thoroughly tested.

I do not believe it a trivial matter to unsex a woman. I do believe that there has been and is now, in some quarters, a tendency to an abuse of the operation of oöphorectomy. Nevertheless my own personal experience and the experience of others having larger opportunity to observe, warrant the opinion that in certain cases this operation is the only remedy which can bring relief to the sufferer. Of course, nothing can be said now as to the results of the operation in the case reported to-night; time must show whether the patient will find relief from her agonizing pain or her epilepsy.

My object in presenting this case, isolated from others, was solely for the purpose of calling your attention to the magic effect of chloral, per rectum, in arresting the vomiting and the pain. For an intelligent presentation of this action from a clinical point of view, it was necessary that I should go into detail as to the circumstances under which it was employed. Of course, it may fail me on further trial under similar circumstances, but there can be no shadow of doubt as to the relation between remedy and result in this case. There can be little less doubt that, but for this remedy, this patient would have been lost. It is not without interest in this connection, that I have, during the past year, in several instances, by the same method of using this agent, secured prompt and complete arrest of the vomiting of pregnancy. Within the past two months I saw a case in consultation, of a primipara at the beginning of the third month of gestation, who pre-

sented all of the phenomena of the pernicious vomiting of pregnancy. During the two weeks prior to my seeing her, she had vomited from ten to fifty times daily. She was now much exhausted and becoming rapidly emaciated; pulse was 120. As she vomited everything that was administered, not excepting even small quantities of cold water, I deemed the administration of remedies by the stomach out of the question; I therefore ordered the rectum to be washed out and an enema containing forty grains of chloral administered. The vomiting stopped at once. A few days subsequently it returned, but was promptly checked by a repetition of the remedy, since which time she has had no further trouble.

To my own mind, there can be but little doubt that the vomititng, in the case reported this evening, was due to acute peritonitis. The abdominal pain, the rapid pulse, increased temperature, the tympanites, and, finally, the character of the fluid ejected, would seem to settle this question. And yet, the sudden fall of temperature, the prompt and permanent relief of pain, arrest of vomiting—indeed, of all unpleasant symptoms—after the administration of the chloral, might raise a doubt in the minds of some. What explanation may be offered as to the action of chloral in arresting vomiting?

The mechanism and causes of vomiting are not well understood, but enough is known to establish the existence of a vomiting centre in the medulla closely related to the respiratory centre. The afferent impulses may come either from below upward, as in the vomiting of peritonitis, hepatic colic, or gastric irritation; or these impulses may come from a higher source than the medulla, as in the emesis caused by nauseous vapors, by the memory of past odors, taste, or sight, and by cerebral injury or disease.

In ordinary vomiting due to gastric disturbance, the afferent impulse follows the vagus, while the course of the stimulus when the cause is in the uterus or ovaries, is not so well known. From the intimate connection between the sympathetic ganglia of the abdomen and pelvic region, it is supposed that the impulse is conveyed through these to the epigastric region and thence by way of the pneumogastric to the medulla. Since, however, dogs can be made to vomit by the subcutaneous injection of tartar emetic after the vagi are cut, it is evident that there is some other route both for afferent and efferent impulses of emesis. Efferent impulses also travel through the phrenic and intercostal nerves. This additional route has been attributed to the sympathetic nerves, and to the presence of sympathetic ganglia near the cardiac orifice of the stomach, which are presumed to furnish the nervous energy necessary for vomiting when the main source of supply is removed by cutting the vagi.

Ordinarily the vomiting of peritonitis, hepatic colic, ovarian irritation, and other abdominal affections, is caused by the reflex stimulation of the normal mechanism of vomiting, and both the afferent and the efferent impulses are carried over the pneumogastric nerve.

In peritonitis the vomiting may be reflex and not due to the regurgitation of intestinal or biliary secretions into the stomach, since violent attempts at vomiting often occur when the stomach and intestines are empty. Besides, when the mesenteric nerves are cut in peritonitis or in intestinal obstruction the vomiting ceases, indicating that the emesis was reflex and that the course of the afferent impulse is through the mesenteric nerves.

Brunton has pointed out that chloral not only diminishes the reflexes in a notable degree, but that it also dilates the vessels of the intestines, exercising at the same time a marked paralyzing action on the nerves. Hence it would appear to answer two very important conditions in the vomiting of peritonitis. First, diminishing the intestinal reflexes which cause the vomiting, and second, partially paralyzing the mesenteric nerves, the route along which such reflex impulses travel. I do not mean here to advise the use of chloral in the treatment of peritonitis as a curative remedy, for its dilatation of the vessels of the intestine is really a contraindication, but its value as a symptomatic treatment in combating this most distressing factor should be appreciated and employed. Opium is apparently curative in this disease, since it will "prevent the reflex dilatation of the vessels which the local irritation would otherwise produce" (Brunton). While opium then must still be our sheet anchor in peritonitis, chloral deserves a trial in those cases in which vomiting becomes a dangerous feature.

In singultus, which probably differs from emesis only in the absence of coördination of all the muscles implicated in the latter, chloral has been recommended and found highly useful, by Brunton, Leavitt, Wood, Stillé, and Kingsbury.

In the vomiting of pregnancy, where the causes are so obscure and probably so various, we are forced to call the trouble reflex in character until its etiological factors are more clearly demonstrated. Certain it is that those remedies and methods of procedure for its treatment which have met with greatest favor are mostly directed toward a diminution of reflex irritation and spinal irritability (under methods of procedure, as above, may be included cervical dilatation, removal of inflammation, uterine displacement, etc.). These actions are possessed in a high degree by chloral, and must, in the absence of any convincing physiological data, account for its value in this affection.

The use of chloral in the vomiting of pregnancy is recommended, especially in enemata by Playfair, Leishman, Busey, Atkinson, Eulenberg, Richardson, of Boston, and Simmons, of Yokohama.

In conclusion, I would state my conviction that, while it should be given in large doses to be effective, it is not safe to employ the rules for rectal dosage usually followed in the administration of dry extracts and less soluble medicines.

If the rectum be cleansed, the dose ordinarily should not be increased more than twenty per cent. above the proper dose in the individual case *per os*.

CLINICAL HISTORY OF A CASE OF HEMORRHAGIC MALARIAL FEVER;

MICROSCOPICAL EXAMINATION OF URINE AND BLOOD; TREATED BY LARGE DOSES OF ARSENIOUS ACID; PROMPT RECOVERY.

BY BENJAMIN HOGAN RIGGS, M.D.,
OF SELMA, ALA.; EX-PRESIDENT MEDICAL ASSOCIATION OF ALABAMA, ETC.

ABOUT 1.30 o'clock, on the morning of Dec. 15, 1885, I was summoned to Eugene B., a white youth, aged over sixteen years, reported as being seriously ill with "yellow chills." It being an exceedingly inclement night, and not feeling well, I declined to go, but gave verbal directions for treatment, and wrote a prescription to be filled at the drug store. This young man had had many attacks of this dangerous malady since childhood, this being the third attack since August last, 1885. He was one of those in whom quinine always caused "hemorrhage from the kidneys" (?). Therefore, I had never been able to use the bark derivatives. In his two previous attacks this year and last year, I had "brought him through" with piperine, Dover's powder, calomel, tincture of iron, and extract of ergot.

His was thoroughly a case of malarial cachexy: he had a spleen as large as a peck measure, hard, sore, and extending down to the crest of the left ilium, and to the right of navel. He had purpuric spots on both legs; and had been under antimalarial treatment since previous attacks, but still had them. When this attack had come on he was taking as a tonic a mixture of ferri et quiniæ citrat., and syrup of ginger, unknown to him, with benefit to general health, but early morning and late night exposure, probably, induced a recurrence at this time. I gave the messenger a mixture of tinct. of chloride of iron, chlorat. potass., syr. lemon and water, about twenty-five drops of the iron at a dose, to be taken every two hours, until I came in the morning; and ordered a full dose of calomel to be taken at once, hot foot bath, and hot bottles in bed to promote diaphoresis.

On morning of 16th I called to see him; found he had had a very bad night: passed large quantities of port-wine urine; was now very sick at stomach; was drowsy; skin dry; fever gone; urine cleared up to the "meal-bran" look when cold; a little deeper color than natural when first passed, but clear; bowels had not acted well; ordered to stop iron mixture, and put on the compound iron and quinine citrate salt in 15 gr. doses to a teaspoonful of equal parts of syrup of ginger and water every two hours; Seidlitz powder to be given at 11 o'clock; hot bath to relieve symptoms of uræmia. Accidentally failed to get a specimen of the urine for examination.

Returned in two hours. Bath had made him feel better; bowels had not acted freely; still much nauseated; vomited matter of deep orange, almost red color, but when mixed with the water of the slop tub was yellow. Gave a hypodermatic of $\frac{1}{4}$ gr. of morphine, and $\frac{1}{120}$ gr. of atropine. Ordered another Seidlitz powder at 1 o'clock.

Was called in a hurry to see my patient at 2 o'clock, with information that he had another chill. I found him again freely passing port-wine urine, very much nauseated, very restless, and with high fever coming on. Ordered the hot bath again, as there was drowsiness, and I feared uræmic poisoning. The baths were taken in an old-fashioned bath-tub with plenty of warm water. I determined now to resort to the compound which was successful in the last two attacks—piperine and Dower's powder, but to add arsenic to it, as I had been informed of its successful use in such cases by Drs. Robert Cochran, Joseph Groves, and Adams, of this county. I ordered the following capsules, supplementing the Dover's powder by the hyoscyamus extract on account of the ipecac of the powder:

R.—Acid. arsenious . . . gr. ¼.
Piperinæ . . . . gr. ij.
Pulv. Doveri . . . . gr. x.
Ext. hyoscyami . . . gr. v.—M.
Five capsules.

Sig.—One capsule every three hours. To be taken during the night and next day.

At 7 P. M. his temperature in the mouth was 105°; pulse 120, full and soft. Commenced the capsules at 8 P. M., and gave another at 11, 2, 5, and 8, same night. ¼ gr. of arsenic in twelve hours.

On the evening of the 16th I found him very sick; passing port-wine urine copiously; complained of pain and soreness in spleen. He says pain in the spleen inaugurated the chill on the previous night. Took a bottle of urine for examination.

17th.—9 A. M., found him much better, but complaining of nausea. Temperature 98°, pulse 116. Renewed the previous prescription; gave capsules at 11 and 2; he thus took $\frac{1}{20}$ gr. of arsenic in eighteen hours. At 6 P. M. to-day, temperature 98°; pulse 104; temperature remained normal. On night of the 16th had passed an ordinary chamberful of the dark urine. Some symptoms of œdema arsenicalis supervened this afternoon; so lenghtened the intervals of the arsenical doses; gave the three remaining capsules of the second five at 8, 2, and 7 o'clock the night of the 17th, thus giving ½ gr. of arsenic in thirty-five hours.

18th.—Doing well; more marked symptoms of arsenical impression. Took a drop of blood from tip of finger for microscopic examination. Patient looked exsanguine.

19th.—At 2 P. M. took another drop of blood from top of left ear for examination.

Patient convalesced after this steadily; was put on pill of citrate of iron and quinine, strychnine, lactopeptine, and arsenic, so as to take $\frac{1}{10}$ gr. arsenic daily; and to take at night a potion containing potassic iodide, ext. ergot fl., and ext. polymnia medalia fl. (bear foot), for the enlarged spleen.

At this writing, January 6, is still on this treatment, and much better. Size of spleen reduced.

I am disposed to believe that full doses of arsenic constitute the best treatment for this fatal disease. It is safe to give it in $\frac{1}{8}$ gr. doses every three hours until the patient is relieved, or the full effect produced. In other words, the arsenic can be pushed safely until the eyes puff and have a purplish ring beneath them; the fingers feel stiff and puff up; the skin burns (to the patient) and itches; the stomach burns and gripes; there are thirst, dryness of the throat, and may

be a degree of constriction; tendency to looseness of bowels. These symptoms immediately disappear upon discontinuing the remedy.

Liquor potassæ arsenitis—Fowler's solution—represents, according to the last edition of the *United States Dispensatory*, nearly 1 grain of arsenious acid to each 100 minims; it takes, thus, one drachm and four-sixths to equal 1 gr. of arsenic. I have no doubt that it would be proper to give this elegant preparation in place of the arsenious acid. Twelve mimims might be given every three hours until some effect was produced, as this corresponds to $\frac{1}{8}$ gr. doses of the acid. The objection to giving arsenite of potassa or soda hypodermatically is its very irritating local effect. Four or five minims diluted with tepid water, in desperate cases, might be given every three hours for a while.

Dr. B. C. Adams, of Liberty Hill, this county, informed me a few days ago that he gave a patient, successfully, $\frac{1}{2}$ gr. arsenic in nine hours—*i. e.*, $\frac{1}{8}$ gr. at twelve, three, six, and nine o'clock, successively, beginning at twelve, noon, and the other $\frac{1}{2}$ gr. during the succeeding night and next day, at intervals of four hours, thus exhibiting 1 gr. in twenty-five hours. Dr. Jos. A. Groves, of Brown's, and Dr. Robt. H. Cochran, of Mortin's, this county, have also used this remedy, in this disease, with satisfactory results.

Appended is the report of Dr. C. J. Clark, who kindly made microscopic examinations of the specimens of the blood and urine which I collected. I was present during the examinations and verified his observations.

"*Dec. 18.*—A drop of blood from the tip of the finger showed normal blood disks, but I should say fewer than in the slides from healthy persons compared with it. The larger portion had the normal shape and size, but others were crenated, and otherwise misshapen, or reduced in size: while there were amorphous particles that might be the débris of red blood-corpuscles. A drop of water was mixed with this blood when first caught on the slide.

"*20th.*—A drop of blood from the tip of left ear, taken on afternoon of the 19th, was placed between two slides and compressed to thin it out, as it was a large drop. The bottom slide examined separately exhibited many blood corpuscles, while the top showed masses of amorphous materials taken for destroyed blood corpuscles, with some illy defined and misshapen disks.

"*17th.*—The urine was examined. A pint of fluid was brought of a dark wine color, looking as if it contained blood in abundance. Several slides were carefully prepared and examined with different powers. Not a blood disk could be found; nothing but a few epithelial cells and tube casts. I should say the color of the urine was due to the destruction of red corpuscles and the discharge of the hæmatin through the kidneys.

"Different powers were employed in these investigations, varying from 400 to 1600 diameters. Doubtless, in other cases with much engorgement of the kidneys, red corpuscles are discharged in the urine, along with a large amount of hematin from disorganized red corpuscles."

In 1869, Dr. H. S. Hudson, now of Summerfield, Dallas County, Alabama, and myself, made some microscopic examinations of blood taken post mortem from the portal vein, of a colored female dead of this disease, which were published in the *Richmond and Louisville Medical Journal* of July, 1870. We found the blood mass to be remarkably dense (as there was very little blood left in the body) and homogeneous. The blood corpuscles were deficient in number, irregular, and shrivelled. There were also a great many dark granules discoverable on the slides.

Prof. Joseph Jones, of New Orleans, examined a specimen of this urine, and reports as follows: "As a result of this examination, therefore, we have a urine of low specific gravity, loaded with casts of the tubuli uriniferi, filled with hæmatin, deficient in urea, abounding with biliary acids, coloring matter, and containing a small amount of albumen. I was astonished at the amount of bile contained in the specimen of urine, and the solid matters of the urine appeared to be chiefly those of bile."

EXTRAUTERINE PREGNANCY CHANGED TO INTRAUTERINE BY THE GALVANIC CURRENT.

BY AUGUSTUS STABLER, M.D.,
OF LAWRENCE, MASS.

SINCE reading Dr. Garrigues's article in THE MEDICAL NEWS of December 12th, on "Extrauterine Pregnancy Changed to Intrauterine by Faradization," there has occurred in my practice a similar case.

Mrs. ——, aged thirty, the mother of four healthy children, last menstruated August 12th. In September, at the expected time, the flow did not appear, but she suffered with all the other symptoms peculiar to the menstrual molimen: headache, disturbance of digestion, a feeling of weight and fulness in the pelvis, with more or less pain in the left side. I did not regard the absence of the flow as of much importance; or, indeed, the other symptoms, as she had always been subject to nervous disturbances at the period.

In November, at the expected time, the flow again was absent, and the other symptoms were intensified and prolonged. She thought her abdomen was growing larger, and feared she might be pregnant, as she was evidently getting fatter. There was, however, no morning sickness, and no apparent change in the breasts, and she had a leucorrhœal discharge, which had been absent in her previous pregnancies. On making a uterine examination I found the os patulous, and filled with the viscid discharge said to be pathognomonic of endocervicitis. This, taken in connection with the leucorrhœa, which did not come from the vagina, as no inflammation of the vagina was discovered, seemed to make it pretty clear that her symptoms came not from pregnancy, but from endocervicitis. I cautiously inserted the sound, and it passed in the normal direction, without any undue force, a distance of two and three-quarters inches. It was not followed by the expulsion of any fluid, little, if any pain, was caused, and the sound on withdrawal was entirely free from any stain of blood.

The examination satisfied me that there was no fœtus *in utero*, and the patient being quite fat I did not succeed in demonstrating any tumor in the abdomen.

In the absence of better proof of extrauterine

pregnancy, I determined to treat the endocervicitis. Applications of tincture of iodine and of nitrate of silver were made to the interior of the uterus. I also punctured the cervix with a tenotome and withdrew about an ounce of blood. Glycerine and tannic acid on cotton balls were placed in the vagina in contact with the cervix. This local treatment seemed to give temporary relief to the backache and leucorrhœa.

Having recently read of the success of Dr. Paul Mundé and other gynecologists with the galvanic current as a means of reducing chronic inflammations of the uterus, I determined to give it a thorough trial in this case, especially as her husband had a good battery in the house and was skilled in its manipulation. After providing him with an electrode that would enter only the length of the cervical canal, and instructing him in the method of its insertion through the speculum, I allowed him to make applications of a weak current from the negative pole, for fifteen minutes every night. These applications never caused her any pain, but, on the contrary, quickly relieved the flatulency to which she was subject, and were always followed by a good night's sleep. She thought the electricity was doing her much good.

About one week before the next menstruation was expected, I directed the interrupted current to be given in place of the continuous, hoping by this means to stimulate the dormant menstrual function, and bearing in mind that, in case of extrauterine pregnancy, this treatment would be the most likely to give good results.

On December 4th, the husband exposed the cervix with the speculum, and was preparing to apply the interrupted current for the first time, when by accident the patient touched the electrode with her fingers, and receiving a shock from it she refused to allow it to be applied to the uterus: the husband told me, subsequently, that he then noticed that the uterus had undergone a change. The cervix was broader and softer, and more easily reached than it had been at previous times, and there was a small light-colored object protruding slightly from the os, which he now supposes to have been a portion of the fœtus, probably the foot.

The next day, December 5th, she reported that the expected flow had come on a little ahead of time, but was attended with considerable pain. I ordered a saline purge, and insisted upon rest in the recumbent posture, and avoided all examinations or applications. The flow continued to appear and disappear, at irregular, short intervals, for about a week, until December 12th, when she had a fall in going down steps, which was followed immediately by severe pain, and about twelve hours after the fall a quantity of clotted blood was expelled through the vagina.

On the night of the 13th, the day after the fall, I was called in haste to her bedside, and found that, with very little effort, she had expelled a dead fœtus enveloped in its unruptured membranes, with placenta and appendages all perfect. The fœtus was apparently of about four months' development, which would correspond with the time elapsed since last menstruation. The woman has made a good recovery.

To sum up: What are the facts which are known in the case?

1. There was no fœtus *in utero* November 18th, as evidenced by the passage of a large Simpson's sound to the depth of two and three-quarters inches without causing pain, bleeding, or the expulsion of fluid; also evidenced by the fact that applications of tincture of iodine and nitrate of silver to the interior of the uterus caused no untoward symptoms.

2. It is probable that there was no fœtus in the uterus until December 4th, as applications of the galvanic current were regularly made to the interior of the cervix up to this time.

3. There was a fœtus *in utero* December 4th, as evidenced by the change in the position and shape of the cervix, as observed by the husband, the protrusion of a light-colored object, and the occurrence of slight hemorrhage next day, which continued at intervals, until the expulsion of the fœtus was hastened by the fall.

How are we to account for the slipping of the fœtus into the uterus after having been previously located elsewhere—probably in the Fallopian tube?

Dr. Garrigues thinks that the faradic current in his case was the efficient agent. In a case reported by Dr. McBurney, as in my case, the galvanic current was employed. Dr. Garrigues, in his able article, does not offer any rational explanation of the *modus operandi*, beyond the possibility that the fœtus may have been reduced in size by the current. I think a more rational theory is that the current induces, as is well known, contractions in the muscles through which it passes. That it is capable of inducing contractions in the uterus, is well known, and may it not also produce contractions in the hypertrophied walls of the tube? The contractions of the uterus may have a tendency to dilate the uterine orifice of the tube, as they do the os uteri, and, at the same time, the contractions set up in the tube may urge on the fœtus, and cause it to protrude into the uterine cavity.

Since writing the above I notice a letter by Dr. Paul F. Mundé, in THE MEDICAL NEWS of December 26, 1885, in which he gives substantially the same explanation, except that he holds, as a prerequisite to success, that the tubal orifice should be already dilated. This may have been so, but I do not think it was, when the galvanic current was first applied in my case. When applied in a weak current for a considerable length of time, it is well known that galvanism increases, in the neighborhood of the negative electrode, the excitability of motor nerves, as well as the nutrition and contractile power of muscle, and may thus induce increased development of the muscular fibres of the tube.

8 CHARLES STREET.

HOSPITAL NOTES.

AURAL CLINIC OF NEW YORK EYE AND EAR INFIRMARY.

Service of DR SAMUEL SEXTON.

ACUTE INFLAMMATION OF THE MIDDLE EAR TRACT.

[Reported by DRS. W. A. BARTLETT and C. J. COLLES.]

THE following seven cases of acute inflammation of the middle ear tract are of interest, representing, as they

do, a group of cases which respond readily to a very simple course of treatment, by which various instillations and vigorous syringing, so often injurious, are avoided, and shown to be quite unnecessary, a cure being brought about, and pain effectually relieved, by simple remedies internally administered.

Case I. *Otitis media purulenta acuta. Marked constitutional disturbance, fever, and very severe pain. Relief in twenty-four hours from administration of aconite and belladonna. Patient discharged cured in one week.*—*Feb. 11.* Female, æt. eight, had pain in left ear, with discharge, two years ago. She attends a public school, where she is constantly exposed to cold draughts of air from the windows, which are opened to admit fresh air into the room when overheated by the steam radiator. Three days ago, after attending school, patient complained of pain, tinnitus, and deafness in her right ear, accompanied by marked constitutional disturbance, nausea, vomiting, and fever. Pain also in the left ear this morning. On examination, the membranæ tympanorum were found to be intensely and uniformly hyperæmic, denuded, and bulging; no perforation, however, being visible. Patient could hear ordinary voice in both ears. She was restless and in much pain. Temperature 102.2°, pulse 130. The treatment consisted of minute doses of tincture of aconite and extract of belladonna, given at frequent intervals, to control the pain; calx sulph. (gr. $\frac{1}{30}$) every two hours. It was hoped that the inflammation would take a regressive course, and paracentesis, therefore, was not performed.

12th. The right membrane has been ruptured, the pain has subsided, and there is a watery discharge. Aconite and belladonna discontinued.

14th. Patient has been resting well, and is free from pain. The discharge from right ear is more profuse, and of a purulent character. Canal syringed, and powdered boracic acid insufflated. The left canal is red and tender, the membrane fleshy and bulging slightly, but no perforation. Continue calx sulph.

15th. Condition improved and discharge diminished. Boracic acid insufflated. Left membrane less bulging and injection subsiding. Calx sulph. (gr. $\frac{1}{30}$) every four hours.

18th, No discharge from right ear; canal filled with dry powder. The left membrane is clearing up. Calx sulph. discontinued.

Case II. *Neglected case of otitis media purulenta acuta, and periostitis externa. Catarrh of upper air-tract. Decayed teeth. Poor physical condition. Discharged cured in fourteen days.*—Male, æt. fourteen, is a subject of nasal catarrh, and has suffered at times from pain in left ear, during past month constantly, in addition to which has been troubled with tinnitus and deafness in the same ear. After an exposure, eight days ago, left ear began discharging, accompanied by swelling and pain in the mastoid region. On examination the left membrana tympani is found bulging, injected, and fleshy in appearance. By the Valsalvan experiment, pus is forced through an opening in the posterior inferior segment. The left auricle is unduly prominent, owing to an extension of the periostitis externa, and there is a fluctuating swelling over the mastoid. Patient hears ordinary voice with left ear. Right ear normal.

The treatment was the same as in Case I. The abscess was incised. Pain ceased entirely in two days, and discharge in five. Two weeks afterward the left drumhead was found to be healed, but opaque and lustreless; patient could, however, hear low voice distinctly with left ear.

Case III. *Acute inflammation of attic and membrana flaccida. Severe pain, relieved in two days. Discharged, cured, in two weeks.*—Male, æt. eight. No previous ear trouble. For past five weeks much pain, at times very severe, in right ear, with scanty discharge. Loss of sleep and appetite. On examination free purulent discharge from right ear is found, and only the membrana flaccida of drumhead is seen, the same being fleshy in appearance and concealing the upper segment of the membrane. Hears ordinary voice with this ear. Left ear normal.

Aconite and belladonna were given to allay pain. Calx sulph., at first every two hours, afterward less frequently. Pain subsided in two days, and discharge ceased in eight. Fourteen days later the canal dry, and drumhead (right) resuming rapidly its normal condition.

Case IV. *Foreign body in ear, subsequently acute otitis media purulenta, caused by sea-bathing. Carious teeth. Severe pain, relieved in two days. Discharged, cured, in eight days.*—Male, æt. eighteen, had a pea removed from left ear about ten years ago, and since then hearing in that ear impaired. Twenty-four hours subsequent to sea-bathing five days ago, patient complained of pain, tinnitus, and deafness in left ear, which have prevented sleep. Yesterday first noticed discharge. On examination the walls of left meatus externus are found swollen and denuded; the drumhead inflamed and bulging, with small perforation in the posterior inferior segment. Only loud voice heard in left ear. Right ear normal. Catarrh of upper air-passages not marked. One carious tooth in left lower jaw.

The treatment here was the same as in Cases I., II., III. Pain had entirely ceased by the second day, the discharge being copious. The latter, however, ceased by the eighth day, when drumhead was found to be clearing up.

Case V. *Acute inflammation of the middle ear. Autophonia. Pain relieved in three days.*—Male, æt. twenty-seven, has long been subject to earaches. Head catarrh not marked. Whilst working is obliged often to stand knee-deep in water. For the past week pain and throbbing in left ear, accompanied by autophonous phenomena. Has used instillations of laudanum, but with no relief from pain. The examination shows left canal with muco-purulent matter, the drumhead fleshy in appearance with a small perforation in the posterior inferior segment. Hears ordinary voice with affected ear. Right ear normal.

Treatment as in previous cases. Pain and discharge had ceased by the third day. The dry powder in canal was left undisturbed for a time.

Case VI. *Acute purulent inflammation of both middle ears. Frequent "colds." Rhinitis. Hypertrophied tonsils. Carious teeth. Discharged cured in eleven days.*—Female, æt. eight, long subject to colds in the head, toothache, and pain in the ears. After exposure four weeks since, had pain, tinnitus, and deafness in right ear, followed shortly by a discharge. These symptoms ceased in one week, but reappeared

three days ago, accompanied by pain and a discharge from left ear.

Both canals were found filled with purulent matter. The right drumhead not seen, the left uniformly congested and bulging. Ordinary voice heard in both ears. Rhinitis marked and tonsils hypertrophied. On the right side of lower jaw were two carious teeth.

The same treatment as in the other cases was followed. Pain had entirely ceased by the second day. Insufflations of boracic acid powder were made every third day, and by the eleventh day the discharge had ceased. Patient regained normal hearing in three weeks.

Case VI. *Acute purulent inflammation of middle ear. Severe pain, relieved in two days.*—Male, æt. three. No previous ear trouble. For past five weeks child has been suffering with pain in right ear and discharge. Pain especially severe during last few days.

On examination right canal found filled with purulent matter. Membrane could not be seen. Hears ordinary voice with right ear, low voice with left,

In this case also the treatment mentioned above gave satisfactory results, the pain having entirely ceased in two days, the discharge being very slight. Fourteen days later, when patient was next seen, the canal was found to be dry and the membrane clearing up. There had been no discharge for several days. Patient could hear low voice in affected ear.

It is notable that in the case where inflammation was confined to the attic mainly there was less deafness than where the antrum was the principal seat of trouble.

MEDICAL PROGRESS.

Chromic Acid in Diseases of the Upper Air-passages.—Rethi records the use of chromic acid as a caustic application in over sixty cases, including chronic hypertrophic rhinitis, adenoid vegetations in the nasopharynx, chronic hypertrophic pharyngitis, and circumscribed swellings in chronic laryngeal catarrh. One or two crystals of the acid are placed on the end of a silver sound, which is then gently heated to remove all water of crystallization. If the heating be too rapid, or be continued till the film formed at the end of the sound assumes a green tint, the caustic properties of the acid are lost. Prior to the application the parts affected are washed with a 5 to 10 per cent. soda solution, which washing is repeated after the burning. No evil after-effects were noted in any case.—*Centralb. f. Chirurgie*, Jan. 2, 1886.

The Nature of Nerve Force.—In contradiction to the view that nerve fibres are fatigued by the transmission of stimuli, Bowditch, of Harvard, has, in the following experiments, conclusively shown the absence of such fatigue in the nerves of warm-blooded animals.

A cat was etherized, and the sciatic nerve divided near the sacrum. A pair of shielded electrodes was then placed upon the same nerve lower down in the thigh. The tendon of the tibialis anticus was dissected out and connected with a lever which recorded the contraction of the muscle on the smoked paper covering a cylinder revolving once in twelve hours. The secondary coil of an ordinary induction apparatus was then connected with the electrodes and the minimum intensity of stimulation requisite to produce a tetanic contraction of the muscle was determined. The animal then received a dose of curare (0.007–0.01 grm.), sufficient to prevent muscular contractions, and the irritation of the nerve was steadily maintained while the animal was kept alive by artificial respiration. In the course of an hour and a half to two hours the curare was so far eliminated that the stimulation of the nerve, which previously had been without effect, began to produce muscular twitches which, as the elimination of the drug progressed, became more frequent and more violent. A true tetanus, however, was never observed.

In some of the experiments a second dose of curare was given, when the muscle began to twitch, and the experiment continued till the drug was a second time eliminated. In this way it was found that stimulation of the nerve lasting from an hour and a half to four hours (the muscle being prevented from contracting by curare) did not exhaust the nerve, since on the elimination of the curare the muscle began to contract.

Physiologists have long been in the habit of comparing nerves to telegraph wires, since they seem to be indifferent conductors transmitting impulses equally well in both directions.

It would appear from these experiments that the absence of fatigue in consequence of activity is another very interesting point of resemblance.—*Journal of Physiology*, vol. vi. No. 3.

Removal of Thyroid Body.—Horsley has presented before the Société de Biologie the results of his observations upon the effects of the removal of the thyroid body in monkeys. In the animals so treated the wound healed by first intention, death occurring, however, in from five to six weeks, with all the symptoms of myxœdema. There is at first a trembling of the hands, analogous to that seen in exophthalmic goitre, later functional paralysis, resembling paralysis agitans, with the early appearance of cretinism, then death, with sudden fall of temperature.—*Gazette Hebdomadaire*, Jan. 8, 1886.

On the Action of Antipyrin upon the Temperature and Tissue Changes of Children during Fever and in Health.—Dr. Jacubowitsch has detailed his observations upon the use of antipyrin in the following eleven cases, viz., four of typhoid, one of tubercular meningitis, two of miliary tuberculosis, and four children in good health. The experiments appear to have been conducted with thoroughness and care. The dose given within twenty-hour hours varied from 15 grains to a child of two years old, to 105 grains to a healthy child of seven years. The following were the results: Antipyrin lowered the temperature in all cases, but to a very slight degree in the healthy children. The amount of fall in the temperature did not always depend on the dose. After even the largest doses, the temperature did not remain at its lowest point for more than twenty hours. The greatest fall occurred about midnight, after which the temperature gradually rose. In healthy children, even large doses fail to lower the temperature to the same extent as in the feverish. Young children take large doses well for from one to two days. In most of the cases the quantity of urine was diminished to the extent of nearly one-half; it was very concentrated, and the specific gravity was increased. The

quantity of urea, uric acid, sodium chloride, phosphoric acid, and sulphuric acid was notably diminished during the use of antipyrin. Forty-eight hours after the last dose, the daily quantity of all these urinary constituents was greater than before the drug was given. The author feels some hesitation in recommending the use of antipyrin in fever cases, because, in spite of its undoubted antipyretic power, it could not safely be used for any length of time, if the remarkable retention of the products of oxidation which he observed is confirmed by further experiments.—*Edinburgh Medical Journal*, February, 1886.

The Use of Oil of Turpentine for the Removal of Insects from the Ear.—Köhler, of Posen, has for six years discarded the use of tobacco, chloroform, and instruments in the removal of minute insects from the ear. He recommends that the head be inclined to the sound side, and the external meatus filled with oil of turpentine, which should be allowed to remain for five minutes. At the expiration of this time the ear is washed out with a syringe, with the almost constant result of removing the intruder.—*Revue de Thérapeutique*, Jan. 15, 1886.

Antipyrin and Calomel Compared in Pneumonia.—The *St. Petersburg Weekly Clinical Gazette* publishes some observations which have been made by Dr. Posadski, under the direction of Prof. S. P. Botkin, on the comparative results of the antipyrin and calomel treatments in croupous pneumonia. He thus treated a group of twenty-five cases with antipyrin alone, giving from half a gramme to two grammes (seven and a half to thirty grains) for a dose, and one to eight grammes (fifteen grains to two drachms) per diem. A second group of twenty-three cases, as similar as possible to those of the first group, was treated with calomel in doses of one-eighth of a grain four times a day. The average age of the patients in the first group was twenty-seven years and a half, and that of those in the second twenty-five years and a half. Those treated with antipyrin retained their full consciousness, but in the course of two or three days failed greatly in strength, the heart's action becoming exceedingly weak. They suffered from cough, and with difficulty expectorated a small quantity of slightly tinged sputum. After the first few doses there was a fall in the temperature, but not of a permanent character; sometimes, indeed, there was no fall at all, and when there was, notwithstanding the continuance of the drug, a rise followed. The crisis took place with a fall of temperature on the average on the seventh day of the disease, the mean number of days of fever being 8.1, but the local physical signs lasted 13.5 days. Complications occurred in nearly all the cases, sometimes being of a serious nature, collapse even being noted. In the urine there was nearly always albumen in considerable quantity, also antipyrin. The fall in weight averaged 20.34 zolotniks (about twenty-seven ounces), which was less than the mean fall of the patients treated with calomel, but the latter recovered their weight more rapidly during convalescence. When the doses of antipyrin were frequent, vomiting was often induced, and in two cases an antipyrin rash made its appearance. Those treated with calomel frequently presented a typhoid condition, and in some cases there was delirium. They were not much distressed by cough, the sputum was expectorated easily and in considerable quantity, and they did not suffer from sweats. The temperature rose high. The mean duration of the fever before the critical fall was 7.1 days, which was generally accompanied by drenching perspiration. The local physical signs lasted on the average nine days (against 13.5 in the other group). There was rarely albumen in the urine, and when it existed there were only traces. Complications were infrequent. The general conclusion arrived at was that antipyrin, in spite of its power of reducing fever, has no beneficial effect on the course or result of the disease.—*Lancet*, Jan. 30, 1886.

Hopeine as a Hypnotic.—Eloy records several cases in which hopeine was employed with advantage as a hypnotic. The mean daily dose for an adult was found to be three-tenths of a grain, and was best administered in pill form. Eloy summarizes his results by describing hopeine as a fairly reliable hypnotic, of relatively slight toxicity, which is indicated in cases where opium cannot be prescribed, and which is useful in insomnia where pain is not the cause.—*L'Union Médicale*, Jan. 23, 1886.

Effects of Cocaine on the Central Nervous System.—In a paper read before the Chicago Medical Society, Dr. D. R. Brower thus summarizes his experience as to the use of cocaine in various neurotic troubles:

1. Cocaine, in small or moderate doses, is a cerebral stimulant, but produces derangement of the digestive and assimilative functions, and diminishes the elimination of waste products.

2. The use of cocaine in the alcoholic and opium inebriates is not satisfactory; while it is a more or less perfect substitute, yet its use is attended with greater danger than alcohol or opium.

3. The use of cocaine in mental depression, if we carefully guard against the depressing effects of the drug upon digestion and assimilation, will often give better results than any drug hitherto used.

4. The use of cocaine in neurasthenia is a valuable addition to the treatment.

5. The drug, if administered in large doses persistently, causes a very marked deterioration of the central nervous system, producing a profound cerebral neurasthenia, and may produce such a malnutrition of the cerebrum as to develop insanity.

6. Cocaine, occasionally, in doses heretofore regarded as small, produces alarming depression of the central nervous system.—*Am. Prac. and News*, Feb. 6, 1886.

Antidysenteric Powder.—The following formula is praised by Schmitjan, as being laxative and antiseptic, and at the same time possessing a beneficial topical action upon inflamed and ulcerated surfaces, comparable to the action of the sulphurous waters:

Sulphur, sublimed and washed,	
Powdered fennel seeds . . .	āā 1 part.
Powdered sugar,	
Powdered gum-arabic . . .	āā 2 parts.

Mix. A teaspoonful every three hours, in the subacute or chronic forms of dysentery. The treatment is commenced by an emetic of ipecac.—*L'Union Médicale*, Jan. 17, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET.
PHILADELPHIA.

SATURDAY, FEBRUARY 27, 1886.

THE PHYSICAL SIGNS OF MITRAL STENOSIS.

IN THE NEWS of Feb. 6th we referred to certain problems in the general pathology of mitral stenosis, and we propose, on this occasion, with the help of the valuable papers of DRS. FLINT and BROADBENT, in the *American Journal of the Medical Sciences*, Jan. 1886, to discuss briefly the physical signs of this important condition.

While, as a rule, practitioners readily make a diagnosis in cases of mitral regurgitation or of aortic valve disease, the reverse may be said to hold good of mitral constriction, which, as Broadbent says, presents greater difficulties in diagnosis than any other disease of the valves. And yet, in many instances, when once the characters are known, no affection is more quickly or more easily recognized. The chief trouble arises from the fact that the physical signs in a given case may be variable at different times, and unless this is understood serious confusion may result. Broadbent's careful study of this condition has led him to recognize three stages of the disease. In the first stage, not much change is noticed in the dimensions of the heart, but the pathognomonic sign is a rough, blubbering, vibrating murmur preceding the first sound and heard in a limited area at the inner side of, and usually a little above, the apex beat. On palpation a thrill is perceptible to the hand at the same spot. The peculiar limitation of the murmur and thrill is one of its most remarkable characters. By the great majority of writers the rough presystolic bruit is held to be distinctive of mitral stenosis, but Flint brings forward evidence to show that in very rare instances it may be present without constriction of the orifice. As a result of backward-pressure in the pulmonary circulation, the second sound at the second left costal cartilage is accentuated, and from a lack of synchronism in the closure of the aortic and pulmonary valves there may be reduplication. To these well recognized signs Broadbent adds another, the intensification of the second sound at and beyond the apex.

The second stage is characterized by the disappearance of the second sound at the apex and by the short sharp valvular character of the first sound, which, in reality, resembles closely the second sound. Indeed, as Balfour pointed out, the mistake is very commonly made, and the murmur is regarded as a rough systolic, followed by a sharp second sound. It may be extremely difficult, in these cases, to determine accurately the relation of the sounds to the cardiac systole, particularly if the action is rapid, but by finding a spot where both sounds are audible and distinct, and following them from this point, it can usually be determined which of the two disappears as the apex is approached. A satisfactory explanation of this remarkable alteration of the first sound has not been given. It is much more intense and valvular than when the mitral curtains are normal. Flint holds that it is due to the changes in the valves; Broadbent ascribes, and, we think, more correctly, the modified sound to the ventricular wall. The ventricle is imperfectly distended, and at the first movement of contraction the walls meet with no resistance, but are "suddenly brought up and made tense when resistance is encountered, and so produce the sharp sound." The disappearance of the second sound at the apex is accounted for by the overlapping of the left ventricle by the large right chamber, which occupies the apex, and thus prevents the conduction of the aortic sound to the surface; and, again, the diminished output of the left ventricle does not fully distend the aorta, and the recoil on the valves, which causes the sound, is consequently weak. In this stage there may also be heard a mitral diastolic murmur, preceding the pre- or auricular-systolic murmur, and corresponding to the period of active dilatation of the ventricle. As Dr. Flint remarks, this murmur claims more attention, clinically, than it has hitherto received.

The third stage is characterized by the disappearance of the presystolic murmur altogether, and there is heard only the loud, sharp, first sound and, perhaps, a systolic tricuspid murmur. The true state of affairs may now be completely overlooked in the absence of a murmur and of marked hypertrophy. Broadbent states that he has known the heart at this stage to be pronounced normal. There can be no question of the very common disappearance of the presystolic murmur in the late stages. Cases are frequently sent to the post-mortem room in which the murmur has been absent during the stay in hospital, and yet the

mitral constriction has been marked. And again, in cases admitted with pulmonary complications or dropsy, the presystolic murmur may not be present on admission, but may develop under observation, as the serious symptoms subside. Broadbent attributes the disappearance of the murmur to the establishment of tricuspid stenosis, and reflux into the right auricle, which so lowers the pressure on the pulmonary veins and left auricle that the force of the current through the mitral orifice is not sufficient to generate sonorous vibrations.

The condition of the mitral segments in stenosis is such that complete closure during ventricular systole is impossible, and we must suppose more or less regurgitation. A systolic murmur is not, however, always audible, though it can sometimes be developed when the vigor of the heart's action is increased by exercise. But there may be no regurgitation even when the valves are quite incompetent, for the pressure in the auricle may be such that no reflux of any moment can take place into it and the blood from the ventricle escapes more readily into the aorta, where there is a minimum pressure.

So long as the presystolic murmur is well marked and both sounds can be heard to the left of the apex, patients with mitral stenosis do not appear to suffer much inconvenience, and Dr. Flint testifies to the tolerance of this state for years. In the second and third stage, though not necessarily attended with serious symptoms, the patient suffers more or less inconvenience, and there are evidences of an embarrassed circulation.

What seems so clear and distinct on paper may, however, present an inextricable problem when the stethoscope is placed over a rapidly acting heart, but in any case the difficulty in diagnosis will be materially lessened by a careful study of the directions so admirably laid down by Dr. Broadbent.

DILATATION OF THE UTERINE CAVITY.

DILATATION of the cervical canal is an operation not unfrequently required for diagnostic or for therapeutic purposes; in the former, for example, for the recognition of a neoplasm in the uterine cavity, and in the latter to make its removal possible, or for the removal of remnants of the ovum therein remaining after miscarriage or labor. This dilatation was, for a time, very generally effected with sponge tents, but the danger of septicæmia has led to their almost entire abandonment. Sea-tangle in some degree displaced sponge, but now most of those who use gradual dilatation prefer tents of tupelo. But there is an objection to all three of these in the fact that the dilatation requires several hours, or, it may be, two or three days, and the longer the period occupied the greater the danger of septic infection.

The late Dr. Peaslee, many years ago, devised a series of metal dilators, but these were more for local effect than for obtaining ready access of fingers or instruments to the uterine cavity. Hegar has made hard-rubber dilators, conical at the uterine end, and having the external end flattened so as to form a handle. Independent of the handle, they are five or six inches in length, and several constituting the set, their successive increase in diameter is only one millimetre; they are numbered so that they may be used in continuous order until sufficient dilatation has been accomplished. The dilators are thoroughly washed and disinfected after being used: when again employed they are dipped in a five per cent. solution of carbolic acid, and each one, before its introduction, is covered with five to ten per cent. carbolized oil. In general, an hour, often less, is sufficient time in which a dilatation permitting the introduction of the finger into the uterine cavity, is accomplished. Hegar justly observes that the advantages of this practice are evident. Complete dilatation is made much more rapidly than with the sponge or by other means, and is much more agreeable for the physician, and especially for the patient. The antiseptic method can be strictly applied. The hard-rubber, which is smooth, does not present the inconveniences of dilators that change in volume. The brief duration of the operation, greatly lessens the danger of infection. Having used Hegar's dilators several times, we greatly prefer this method to that of dilating with any of the various tents.

Quite recently, another method of dilating claims professional attention: it is called "the new method of Professor Vulliet to effect dilatation of the uterine cavity, in conditions which permit direct inspection of this cavity," and is described by BÉTRIX in the January number of the *Nouvelles Archives d'Obstétrique et de Gynécologie*. In this method the patient occupies the knee-chest position, and the perineum is lifted up by a Sims's speculum, as large a blade as possible being used; the next step is by means of a uterine sound, or a urethral bougie, or some similar instrument, or a two-bladed dilator, to begin the process of dilatation. Following this, is the introduction into the uterus of iodoform cotton tampons; these are small, none larger than an almond, and have been prepared by having a double thread passed through each, after which the cotton is dipped in a 10 per cent. ethereal solution of iodoform, dried rapidly, and then kept in a well-stopped flask.

One after another of these cotton balls is pressed into the uterus until the cavity is filled; the threads hang out of the vulva and may be tied together so that all the tampons may be removed at once. They are left in the uterine cavity for twenty-four, or even forty-eight hours, when they are removed; if necessary, the cavity is washed out and fresh tampons, in a greater number, introduced; these in turn are removed

and others introduced, the number being each time increased. If a rapid dilatation is necessary after the first applications of the iodoform tampons, the uterine cavity being in a state of complete asepsis by the former means, laminaria may be used, three or four of such tents being introduced in a single bundle. But the laminaria causes more pain than the cotton, it necessarily produces some traumatism, and it is impossible to have the tents completely aseptic; the cotton alone will always cause complete dilatation, though requiring a much longer time than when assisted by the means just mentioned. When the dilatation is completed and has been regularly made, the neck is effaced as completely as it is at the beginning of labor.

The time required for dilatation varies according to the state of the uterus and the degree of the resistance of the neck; in one case of fibrous polypus, the interior of the uterus was visible on the third day, in a case of cancer nine days were required, while in a third patient it was not until after five weeks' dilatation that this end was attained; usually a period of fifteen days is necessary.

After such dilatation photographs of the interior of the uterus have been taken, and also moulds both of rubber and of plaster of Paris have been made.

Such complete dilatation that the entire interior of the uterus is made visible, must be rarely necessary for diagnostic or for therapeutic purposes, and therefore a period of fifteen days, the average time for such expansion, can only very seldom be advisable; in almost all cases a week, or even less will be sufficient time to occupy with this process. Even then the contrast between seven days consumed in finding out what is the pathological condition, and preparing for a suitable operation, seems a very long time in comparison with a single hour which will be occupied in attaining the same ends by Hegar's dilators. Nevertheless, we see that Prof. Vulliet's plan presents some important advantages in certain cases, and it must take its place among the valuable means of diagnosis in some intrauterine diseases, and prepare the way for their appropriate treatment.

RESPONSIBILITY IN THE PREPARATION OF MEDICAL CERTIFICATES.

A SUIT was recently tried in one of the courts of this city against two physicians who, it is alleged, negligently certified to the existence of insanity, through which damages resulted from subsequent confinement in a hospital for the insane. In the city of New York a physician has been sued for reporting, erroneously, as it was alleged, a case of smallpox which was removed to a hospital under the regulations of the Board of Health. It is not proposed to retry these cases in the medical press, or to enter into the merits of the mooted issues which terminated unfavorably for the defendants. The nature of the responsibility of medical men who perform duties delegated to them or required of them by law, is, however, a question in which the whole profession has an interest and it should assert its prerogatives.

The law, in assuming to regulate matters pertaining to the public health, requires that the existence of contagious diseases be reported to a central designated bureau. In the case referred to, a report of a supposed case of smallpox was made, but it turned out that a difference of opinion subsequently existed among the doctors as to the exact nature of the disease, and, although the physician did not convey the patient to the hospital but she was removed there by the Board of Health, yet the learned judge instructed the jury that the doctor started the machinery, and they accordingly brought in a verdict of $500 damages.

The lunacy law of Pennsylvania, aiming to surround the admission of the insane to hospitals by greater safeguards, provides for their commitment on sworn certificates of two physicians. It also provides for the creation of a body of qualified examiners, and defines their qualifications. A conscientious performance of a duty enjoined by law for the preservation of the public health, and the exercise of the functions of a qualified examiner in lunacy by physicians declared by law to be qualified, ought to be accompanied by an assurance of exemption from the consequences of a possible erroneous judgment. It ought not to be assumed that an opinion about a question, in its nature strictly scientific, can be infallible. Is not the overburdened calendar of our Supreme Court a sad commentary on the fallibility of the judgment and errors of the courts below! It can hardly be held, as has been assumed, that a medical certificate which may prove to have been erroneously made was an act in the nature of malpractice. The physician may in the one case perform a compulsory duty, and in the preparation of a lunacy certificate he does not advertise his ability to furnish an unquestionable opinion, but he may do what the law states plainly he is qualified to perform. In the execution of acts which are compulsory or ministerial, unless it can be shown that the physician was guilty of fraud, negligence, or of being a party to a conspiracy, there should be an exemption from penal consequences. The time has arrived when there should be a judicial determination of the privileges and rights of the medical profession in their newly created relations to the community.

In view of the facilities which exist for vexatious litigation, there is much hesitation on the part of physicians to furnish a certificate of insanity, even in cases in which, in their judgment, it clearly exists. Some positively decline, while others do not act until the disease is so manifest that an average juryman may

come to a conclusion. Others are disposed to exact an indemnity bond or charge large fees to cover the risks they feel they assume. A procedure ostensibly intended to protect the sane may in its practical operation become the means of doing injustice to that class of the insane whose only hope of recovery is treatment in the early stage and before decided changes and chronic conditions have been permanently established. It is public policy to encourage prompt treatment of the insane, and the recognition of the earliest symptoms. It is not believed that with the safeguards embodied in the law, with a Lunacy Committee possessing ample powers of inspection, with its doors always open, any serious abuses or mistakes can occur. The profession may, under the circumstances, properly ask the Committee of Lunacy to consider whether some further legislation is not necessary to protect its members from vexatious litigation, or that the Courts, on a proper occasion, will more clearly define and determine their rights, privileges, and exemption from responsibility.

THE USE OF ANTISEPTICS IN LABOR.

THE *Journal d'Accouchements* of January 30th contains a brief report of the Maternité de Liége for the year 1885, by the Surgeon-director, DR. N. CHARLES. Of three hundred and forty-four women admitted during the year only two died; there were fourteen cases of mild septicæmia, but in eighty-five per cent. of the entire number of women delivered the puerperal period was absolutely normal. There were three cases of eclampsia, and also three of placenta prævia; there were ten applications of the forceps, three podalic and two cephalic versions, and eight cases of perforation of the cranium, seven of these being followed by the use of the cephalotribe, or of the cranioclast; beside these, some other operations were done, making in all thirty-six operations. So low a mortality and so slight a morbidity in a lying-in hospital are worthy of attention. Dr. Charles attributes these happy results to the use of corrosive sublimate as an antiseptic, but he especially insists upon the most minute antiseptic precautions from the end of pregnancy, or, at most, from the first time touch is made during the labor.

A recent communication from CHIARA, an abstract of which is found in the first number of the *Nouvelles Archives d'Obstétrique et de Gynécologie*, also urges the importance of antisepsis during labor. The author believes that in order to render the utero-vaginal canal aseptic during the expulsive period, or at the moment of beginning any operation, the spray of carbolic acid should be used, and that after the labor thorough and large washing of the utero-vaginal canal should be made by a corrosive sublimate solution, 1 to 1000, but from this time no examination of the genital organs is performed, and no injections are used.

Notwithstanding the high reputation of Chiara, it is doubtful whether, even in hospital, still less in private, practice, obstetricians will generally adopt the plan of delivery under carbolic acid spray. The exposure, discomfort, and the possible chilling of the patient, are serious objections. Moreover, we would hesitate to use so strong a solution of the corrosive chloride as advised by Chiara, fearing possible poisoning, and, besides, there is good reason to believe that a solution not half so strong is equally efficient.

Abstinence from vaginal injections after the thorough cleansing following labor is a part of the practice which will be most readily accepted, for, unless special symptoms occur, there is no indication for such injections.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 18, 1886.

THE PRESIDENT, A. JACOBI, M.D., in the CHAIR.

DR. H. D. CHAPIN read a paper on

RHEUMATISM IN EARLY LIFE.

It is a subject, he said which, in view of its great importance, has not received sufficient attention on the part of the profession. Although generally very insidious in its advances, rheumatism is an affection which is continually crippling children for life. Having stated that his remarks would be principally based on an analysis of 76 cases which had occurred under his own observation, he gave a *résumé* of the opinions of various authorities on the diseases of children in regard to the subject, referring particularly to a monograph of Dr. A. Jacobi, published in 1875, in which it was stated that rheumatism was frequent and insidious in early life. J. Lewis Smith had stated that it is scarcely less common in children than in adults, but that it is frequently overlooked. Most authors, however, seem to think that it is not a very common disease in childhood.

Of the 76 cases referred to, the number of cases at different ages were as follows:

6 months	1
11 "	1
20 "	1
3 years	1
4 "	2
5 "	4
6 "	6
7 "	3
8 "	6
9 "	9
10 "	10
11 "	8
12 "	7
13 "	9
14 "	4
15 "	2
17 "	2

During infancy the disease is, apparently, not very common. In Dr. Chapin's three cases, occurring in infants of six, eleven, and twenty months respectively, however, there were well-marked attacks of acute rheumatism, and the diagnosis was rendered the more positive by the fact that in each of the three instances one or both of the parents had also suffered from rheumatism.

In regard to heredity, he said that it seemed to him an undoubted fact that some state is inherited which will develop rheumatism under favorable conditions. It is a rheumatic tendency, rather than the disease itself, that is inherited, as is the case in syphilis. Having referred to the statistics of other writers, he stated that in the great majority of his own cases either one or both of the parents had had rheumatism.

In early life rheumatism attacks more females than males. Of his own cases, 50 were girls and 26 boys; and in 69 cases tabulated by Goodhart, 42 were in girls and 27 in boys.

As to the part of the body affected, in 43 out of his 76 cases the lower extremities alone were affected, and in 40 of these the knees were involved. In 23 cases both the upper and lower extremities were affected, and in 3 the upper extremities alone. In two cases the plantar surface of the feet bore the brunt of the attack.

Pain, as a rule, is not very severe. In children able to express their feelings, the trouble is described more as a stiffness and soreness of the limbs. There is generally little or no rise of temperature. A decided tendency to repetition was observed, and in one case there were as many as six distinct attacks.

A general feature is marked hydræmia, and this is to be regarded as an important factor both as regards diagnosis and treatment.

The absorbing interest in rheumatism in early life, however, centres about the heart. Senator states that the younger the patient the greater the danger of cardiac complications. Having quoted various other authorities in regard to the frequency of heart-trouble, Dr. Chapin said that in 26 out of his 76 cases, or one-third the whole number, there was organic valvular disease, and in 18 of this number there was a mitral regurgitant murmur. Of Goodhart's 69 cases, 15 had organic disease of the heart, and 5 others had pronounced symptoms of cardiac disturbance. It is worthy of remark that endocarditis is by no means so serious in children as in adults, and therefore it may entirely escape observation. It appears to him, he said, that the heart becomes affected only after several attacks of rheumatism, and hence it can be seen how very important it is to make an early diagnosis of the latter disease, and place the patient under appropriate treatment, in order to ward off subsequent attacks, with increased danger of cardiac complication. The proportion of these cases in which the heart becomes involved, as compared with the proportion in adults, has not as yet been definitely determined.

Chorea, as is now generally recognized, has a direct connection with rheumatism. In thirty-two cases of chorea which he had tabulated in a paper read before the New York Neurological Society in 1883, Dr. Chapin found that twenty-two had been preceded, or were accompanied by rheumatism: and he thought it possible that the two affections, as well as the heart trouble so frequently met with in each, were due to a common cause. In individuals in whom all these are found, the usual sequence is, first, the rheumatism, then the chorea, and finally the cardiac affection. There can be no possible doubt that rheumatic children are peculiarly liable to suffer from chorea. Again, parents with rheumatic tendencies may have children affected with chorea, but not with rheumatism. In many of Dr. Chapin's cases chorea did not appear until after several attacks of rheumatism.

In rheumatism in children the mucous as well as the serous surfaces are liable to be attacked. Goodhart says of tonsillitis, that there is a growing frequency of assertion that it is a rheumatic ailment, generally as preceding the attack. Dr. Chapin had met with fifteen instances in which acute tonsillitis appeared before, during, or after attacks of rheumatism. This association of the two affections cannot be proven to be anything more than a coincidence; but it is so frequent as to have attracted the attention of a number of observers.

Having mentioned other complications which he had seen, such as pleurisy (in some cases), cellulitis, and anterior poliomyelitis, he went on to speak of the diagnosis, which, he said, must be generally based on a collection of quite a number of symptoms. We must often depend on what Goodhart aptly calls the composite of the disease. Generally speaking, rheumatism in children is wanting in the severity of any one symptom. One point is, that rheumatic pains usually go from one joint or set of muscles to another. Others to be noted are, the history of the parents, the condition of the heart, the presence or absence of chorea, hydræmia, indigestion, and throat trouble. It is probable that rheumatism is sometimes mistaken for malaria, since it is found that salicylate of sodium will give relief in cases where quinine is not followed by beneficial results. It must not be forgotten, however, that quinine is often very useful as a tonic in rheumatism.

As to the pathology, Dr. Chapin believes that the acid theory is correct. It is probable that two allied acids are concerned in the production of the disease: lactic acid, which is often the result of fermentation from indigestion, and sarco-lactic acid, which is developed in the muscles.

It is highly important to check the rheumatic tendency at the outset, if possible, where it is hereditary, and to this end all appropriate hygienic and preventive measures should be adopted, among which may be mentioned a diminution in the quantity of saccharine and starchy food allowed, and the constant wearing of flannel. In an attack of rheumatism, Dr. Chapin is accustomed to commence the treatment with a dose of Rochelle salt, followed by oil of wintergreen and salicylate of sodium. If any disturbance of the heart is shown, he insists on the most absolute repose in the recumbent position. When endocarditis or pericarditis is present, bodily exercise may be of the greatest possible mischief; as irreparable damage to the heart may ensue if prolonged rest is not secured. This he regards as a point of very great importance. The heart is comparable to an inflamed joint which needs rest more than anything else, and it seems probable that in many cases if the organ can be rested, as far as possible, for several months, the danger of permanent damage may be averted. The long-continued use of such agents as

iron and cod-liver oil should also be resorted to. Dr. Chapin believes that even when valvular disease is present, by appropriate treatment it may sometimes be caused to disappear. At all events, it is of extreme importance that valvular disease should be recognized at the earliest possible period.

DR. JOHN C. PETERS said that the manifest and clearly defined acute rheumatism of children is so much like the same affection in adults that its consideration does not call for special attention. It is the much more common indistinct forms, which none the less give rise to other troubles, particularly cardiac affections, that the profession needs to be especially on its guard against. He thought that the majority of cases show no articular disease, the affection manifesting itself principally in stiffness and soreness in the muscles. Of course, no intelligent physician now ever attends a child suffering from rheumatism without examining the heart every day. He had seen a number of cases of children who merely had a little soreness in the muscles and a little fever perhaps, suddenly taken with shortness of breath and pain in the chest, when an examination of the heart would show the presence of acute rheumatism. He had seen such cases recover perfectly, so far as the general health was concerned. In the course of a year or more, however, there would be a relapse, and then there would be other relapses, and finally the patient would die of valvular and hypertrophic disease.

In chorea he had observed a large number of children with valvular disease. In the same way these patients might recover their general health, but afterward have relapses in the same way as those who suffered from rheumatism.

He then went on to say that he had been in the habit of regarding a large number of catarrhal affections as essentially rheumatic. Rheumatism of the throat is to be recognized by the difficulty of swallowing which characterizes it. In such cases there is usually very little redness or other trouble that can be distinguished by the eye. He had also seen several instances of dysentery where the intestinal trouble disappeared on the breaking out of rheumatism elsewhere in the system, and he regarded the affection under the circumstances as rheumatism of the colon.

Dr. Peters said that there was no doubt in his mind that the acid theory of the causation of rheumatism is the correct one. It is not certain precisely what the acid is, but there is a considerable amount of evidence to show that it is lactic acid.

In the treatment he is in the habit of making potash the basis of all his remedies, as he considers it preferable to soda. He has used tepid alkaline baths with very good effect, and warm powdered chalk is also an excellent application, particularly when there is much perspiration. Phosphate of soda is about the only soda salt which he ever employed in rheumatism. The debility and anæmia which attend the disease are very great, and for the relief of this condition he has found the tartrate of iron and potassa excellent. The potash is also of much service in diminishing the excessive amount of fibrin in the blood in rheumatism. He thought it altogether a mistake to suppose that this alkali is more debilitating to the system than soda.

DR. J. LEWIS SMITH said that he had notes of seventy-three cases of rheumatism in children. Whether there was or was not a *materies morbi*, such as lactic acid, in this affection, he had observed two principal exciting causes, viz., taking cold, and scarlet fever. Inherited predisposition was also common, and he found that it had been specially noted that rheumatism had occurred in one or both parents in eighteen out of his seventy-three recorded cases. One attack of the disease predisposed to others.

Rheumatism is rare under the age of two years, but well-authenticated cases are on record in infants of six months. In most cases of the disease in children, the symptoms are much less severe than in adults. It usually begins in the lower extremities, and then extends upward; but the reverse of this is true in scarlatinal rheumatism, where the trouble begins in the upper extremities, as a rule.

But however mild the attack may be, rheumatism is a dangerous malady in children, on account of the liability to heart trouble which characterizes it. Endocarditis may begin as early as the second or third day, and in one instance he has observed it on the very first day of the attack. If the child escapes this complication for the first week, and proper remedies are administered, the chances are that endocarditis will not occur at all. Dr. Smith said that in 43 out of his 73 cases there was a mitral regurgitant murmur. The endocarditis was usually superficial. One case of embolism has been noted by him as a result of endocarditis. Pericarditis is much more rare than endocarditis, although there is little doubt that it is more frequently overlooked than the latter. Pleurisy, in his experience, is not a very frequent complication.

As to the association of chorea and rheumatism, out of 68 cases of chorea which he had noted, 26 of the patients had had rheumatism one or more times. Usually the rheumatism preceded, but occasionally the chorea set in as early as the latter. Of the other 42 cases of chorea, in 11 one or both parents, and in one other a sister, had had rheumatism. Therefore, in about 50 per cent. of his cases rheumatism was noted either in the patients themselves or in near relatives. Dr. Smith said that he should like to emphasize what had been said about the importance of making an early diagnosis, and placing the patient as soon as possible on the use of proper remedies. By attention to this point, many lives could, no doubt, be saved.

The best remedy is the salicylate of sodium, or of potassium, if the latter is preferred. Dr. Smith was inclined to believe that, as a rule, this remedy is commenced too late, and given in too small doses; the reason for the former being that the diagnosis is not made early enough. If given sufficiently early and in large enough doses, he thought that it would, in a large number of instances, prevent cardiac complications. He recommended that it should be commenced on the first day, if possible, and given in doses of ten or fifteen grains to a child four or five years old. Given in this way, he has come to regard it as a specific. In cases, however, in which the disease had already continued for two weeks, he has been disappointed in its efficiency.

As to the origin of the lactic acid, provided this is the essential cause of rheumatism, he thought that Dr. Chapin was probably mistaken in attributing its formation to fermentation in the processes of digestion, for

the reason that in infants, where lactic acid fermentation is by far the most common, rheumatism is much more rare than in older children, who are much less subject to lactic acid fermentation.

Dr. Malcolm McLean said that he was inclined to believe, that if the minute history could always be ascertained, it would be found that heredity was a factor in every case of rheumatism; the affection constituting the prevailing tendency of the patient's family. Such had been his own experience in quite a number of instances. He had also, like other observers, noted the much greater frequency of the disease in girls than in boys, no less than four out of five of his cases being in girls. This was in part due, he thought, to the style of clothing worn. As to so-called "growing pains," he believed that they are invariably due to rheumatism, and that physicians should on this account not underrate their importance. In some cases of chorea he had observed a condition of accelerated cardiac action remaining, sometimes for years, after the choreic trouble had disappeared, although no cardiac disease whatever could be detected by the most careful examination. This seemed to show an undoubted rheumatic element.

Dr. L. Emmett Holt remarked that typical rheumatism is very rare in children; but if pains be taken to discover it, it will be found that rheumatic disease is nevertheless very frequent in this class of subjects. In these indefinite cases it is necessary to seek out the attendant conditions, and to inquire into the matter of heredity. As to tonsillitis, there is a marked tendency among the later writers to trace a strong connection between quinsy and rheumatism. As to ordinary follicular tonsillitis, however, he doubted whether there is any special connection between the two, as in two hundred cases of the latter he had not been able to find any apparent association with rheumatism.

Dr. Kitch said that he had hoped that in this discussion something would have been said of the connection between rheumatism and the choreic joint affections of children. All the authorities on orthopædic surgery which he had been able to consult, had extremely little to say on this point; but in his own experience he had seen quite a number of cases of diseases of the joints which he believed to have been of rheumatic origin. It is often a matter of some difficulty, however, to make a satisfactory diagnosis between a rheumatic and a tubercular or strumous source of trouble in such cases. Still, he had frequently met with cases of Pott's disease and hip disease, in which there was rheumatism in the parents, and quite recently he had seen one such case in which the child itself was rheumatic and had a direct mitral murmur. He also referred to tarsalgia in children as a rheumatic affection.

The President said that heart disease is very frequent in children, and this is due to two causes, first, sepsis, which is very rare; and, second, rheumatism, which is the cause in the vast majority of instances. The cases of congenital cardiac disease are those of the right side of the heart, and these usually terminate fatally at so early a period of life that it is not necessary to take them into consideration.

As a rule, the younger the child, the less prominent the joint affection in attacks of rheumatism. As to the so-called "growing pains," he thought a word of caution necessary. Dr. McLean had remarked that the diagnosis of growing pains ought never to be made, and that when the parents mention that a child is suffering from such pains, it should always be treated by the physician for rheumatism. It is, no doubt, true that such pains are very frequently of rheumatic origin; but they might be due to other causes also. In the first place, the affection may be a neurosis, and there is sometimes an œdematous swelling about, but not in, the joint. Secondly, there is such a thing as *real* growing pains. When the epiphysis and cartilages are developing rapidly, hyperæmia always results, and this may be so marked as to cause the pain complained of. By this it was to be understood that rachitic epiphysitis was not meant. Sometimes this development in the epiphyses went on very rapidly during and after an attack of such diseases as scarlatina and typhoid fever.

Dr. J. Lewis Smith said, in reference to the acceleration of the heart's action without appreciable cardiac lesion, mentioned by Dr. McLean, that he called to mind a case of this kind, in which the autopsy showed the presence of well-marked endocarditis. Yet during life there had been no murmur whatever. He had presented the specimen to the Pathological Society, and the examination of the heart was made with great care by Prof. Francis Delafield. Endocarditis was not necessarily accompanied by such lesions of the valves as to give rise to murmurs.

Dr. Chapin said that he wished those present would endeavor to assist him in collecting cases in which there had been evident valvular trouble, which afterward entirely disappeared.

The President remarked that there are a certain number of cases in which a cardiac murmur disappears after lasting perhaps only a day or two, or perhaps for a longer period. These are probably instances of simply a rheumatic murmur, and not really of endocarditis. What we take to be endocarditis is in fact rheumatism of the heart muscle. But in other cases there is true endocarditis attended with a murmur, which after a longer or shorter period entirely, or almost entirely, disappears. A heart in which this takes place is not strictly a normal heart, being larger than it should be, but compensation is so ample that no murmur results. This change usually takes place a little after the age of puberty, and it is more likely to occur in males than in females. Dr. Jacobi said he knew of several cases of this kind in the city, where the patients were now grown men, and entirely free from any appreciable cardiac trouble. Dr. Smith had called attention to the fact that endocarditis might occur without valvular disease. This is no doubt true; but in the larger number of cases of endocarditis without a murmur, the disease is probably of an ulcerative character. In the ulcerative form of endocarditis the valves are affected, but the lesion is not on top of the valves, but at their insertion.

The Corresponding Secretary announced the

DEATH OF PROF. ALFRED C. POST,

ex-President of the Academy, and on motion of Dr. John C. Peters, the President was requested to appoint a committee to prepare a suitable memorial of the life and services of the deceased surgeon.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, February 1, 1886.

The President, Samuel Nickles, M.D., in the Chair.

Dr. Thaddeus A. Reamy read a paper on

oöphorectomy for the relief of hystero-epilepsy.

(See page 230.)

Dr. S. P. Conner remarked that although he had never done the operation referred to, he could heartily congratulate Dr. Reamy on the success of his operation, and more especially on the success of his remedy for vomiting. As the paper was being read, however, he had been forced to question whether there was in the case reported a true peritonitis, for the symptoms could all be explained by referring them to reflected irritation. But whether there was or was not inflammation of the peritoneum, it is gratifying to know that we have a remedy which will act so kindly and so promptly in these cases of persistent vomiting. The remedy administered in the manner reported may exert a primary effect on the hypogastric plexus, a secondary effect on the solar plexus, and later on the medulla, its action being increased by its being thrown into the rectum. It was stated in the paper that the patient had taken chloral before, both by the mouth and by the rectum, in twenty grain doses. This would indicate in a measure her tolerance of chloral. The experience of the speaker would indicate that chloral is an exceedingly treacherous remedy, affecting some individuals more strongly in the dose of five grains, than it does others in four times that amount, so that the susceptibility of each individual must be ascertained before a large dose is given. It is the remedy which, above all others, controls spasmodic affections, as is shown by its action in tetanus. The reports of its action, whether it be taken by the mouth or by the rectum, speak very favorably for its use in such affections. It must not be forgotten, however, that chloral sometimes produces very disastrous effects by its toxic action upon the medulla. The dose in this case was small in comparison to the doses that have been administered. The speaker had been particularly struck, in reviewing this subject, by a case reported by Beck, of the Baden army, in which the remedy had been given in the quantity of 420 grains in three and a half hours; the patient slept thirty hours, and recovered. Two hundred grains a day have not unfrequently been administered for days together. The speaker's own experience is not without interest in this connection. He had, when the remedy was first introduced, taken eighty grains of it within forty minutes, for severe headache. He slept ten hours without waking, and then awoke with the most terrific headache he had ever experienced.

In all irritations in connection with either the intestinal canal or bladder, in regions supplied by either the hypogastric or solar plexus, chloral has been found to act very kindly indeed. It had just occurred to the speaker that chloral might be of service in allaying the early vomiting attending strangulations of the intestine, whether internal or external. The only difficulty would be that it tends to mask the very symptoms most indicative of danger, without relieving the difficulty.

Dr. James T. Whittaker remarked that the case which had been reported this evening, has its surgical, its physiological, and its medical aspect. The essayist requests us to consider it only from the standpoints of physiology and medicine. It is a curious thing that facts so common as vomiting and even sleep have never yet received a satisfactory explanation. For his own part, the speaker had become dissatisfied with the explanations of the nature of the process concerned in vomiting. First, it is stated that it is caused by irritation of the pneumogastric; then we meet the statement that it will occur after section of that nerve. Again we read that vomiting is occasioned by the contraction of the muscular fibres in the wall of the stomach; then that it occurs when the stomach has been entirely removed and a bladder substituted. The present prevailing view calls for a special centre in the medulla.

The most varied remedies have been used for the control of vomiting: bismuth, effervescents, creasote, external irritants, etc., but in bad cases the time comes when we must all resort to anodynes. The most effective of the anodynes is morphia;; administered subcutaneously it is usually successful in controlling vomiting. The speaker would not place the same confidence in chloral for the control of vomiting as in morphia. In obstruction or hernia he would not trust it as he would morphia, because in these affections the vomiting has the character of a regurgitation. The better way of relieving this kind of vomiting is, in the judgment of the speaker, to remove the contents of the stomach. Dr. Conner stated a truth when he remarked that chloral is the most powerful agent in controlling spasmodic affections. Any one who has seen its action in relieving the vomiting and cramps of cholera, must agree with this statement. In the last epidemic of that disease which visited this city, he had seen nothing which was equally efficacious. He did not place the same faith as the essayist in the rectal use of the remedy, however; and his scepticism was based on its failure in so many instances to produce the desired effect. A case had come under his observation with the last speaker, where the patient actually died of vomiting, and chloral used in every way had no beneficial effect whatever. He was somewhat surprised by the statement of a previous speaker, that so small a quantity of chloral has produced fatal effects. In the last article he had seen on the subject, by Liebreich, it was stated that a smaller dose than sixty grains had never produced a fatal result, unless impure chloral had been used. It would be interesting to know in these cases what preparation of the remedy had been employed.

Dr. Conner stated that in the vomiting of strangulated hernia, the early vomiting to which he had referred was not due to overfilling of the stomach and bowel, but to reflex irritation, though the latter vomiting is of the retained contents of the canal above the seat of obstruction. Chloral then may, by diminishing or arresting the reflex action, be of great benefit; the danger in using it lies in the arrest of symptoms without in any degree relieving the conditions upon which they depend.

Dr. Samuel Nickles thought there could be no doubt that at the present date the process of vomiting is perfectly understood, and what particular nerve centres control the various muscles which are engaged in a

simultaneous action during the vomiting process. The essayist quoted the remarks of Brunton on this subject, and that author has given a full and clear account of the present state of our knowledge. It has been stated that vomiting is produced by tartar emetic even when the vagus is cut. We can produce vomiting by simply titillating the throat, and by applying certain emetics to various parts of the body. When tartar emetic is injected into the veins or under the skin, a part of it may be eliminated by the mucous membrane of the œsophagus and intestines, and it will, therefore, produce vomiting by its local action, even after the stomach has been removed. It was formerly supposed that tartar emetic acts by exciting the vomiting centre in the medulla oblongata; but when it produces vomiting, a portion of the drug can always be found in the vomited matter. When injected locally it passes through the blood to the stomach to produce its local effect. In a case like that related by the essayist, the vomiting was not produced by an irritation of the stomach, and in the opinion of the speaker it was difficult to see why the remedy administered would not have acted just as well if given by the stomach. It has been stated that when the remedy is injected into the rectum, as in this case, it has a more direct action on the nerves of the abdomen. In the opinion of the speaker, however, chloral injected into the rectum must enter the circulation, pass up through the portal vein, through the liver, through the hepatic vein, get into the right side of the heart and finally into the general circulation before it can reach the nerves of the abdomen, and, in reality, pass through the same course as if taken by the stomach. Unless it is shown experimentally that it acts more directly, he would doubt such a view.

Chloral cannot be well administered hypodermically, because concentrated solutions combine with the tissues and are retained by them. Solutions containing more than ten per cent. are likely to produce local disturbances, and stronger solutions are apt to produce abscess. Diluted solutions can be used, but the dose is so large that several syringefuls must be injected.

Chloral is an efficient agent to arrest certain spasms. We can, for instance, very readily prevent the spasms of strychnia by it. In rabbits, if chloral be previously injected, an ordinary lethal dose of strychnia will not produce tetanic spasms. But chloral will not allay all spasms. It will not allay the spasms of epilepsy; it is largely used in cases of chorea to produce sleep, and during sleep, of course, the spasms cease; in this it is effectual. There can be no doubt, too, that in certain forms of vomiting it would be an exceedingly useful agent in doses not exceeding twenty grains; but the speaker believed the bromide of potassium a better remedy in the vomiting of pregnancy, and an agent which may be given in large doses, in as much as half a drachm or one drachm doses if necessary, without producing any evil effects.

Death has resulted from thirty grains of chloral, and a case was reported in which ten grains were believed to have produced death. The speaker has seen very dangerous symptoms produced by thirty-five grains. The rule laid down in some of the text-books at present is that twenty grains should be the maximum dose at first. This may be repeated in an hour, and it is generally stated that sixty grains may be given in succession. Obstetricians, he believed, place the dose that is required to produce rapid dilatation of the os at fifteen grains, to be repeated twice if necessary.

While chloral is a useful remedy in tetanus, it is still doubtful whether it diminishes reflex action as promptly as does the bromide of potassium. Huseman, among others, is of opinion that its action is chiefly on the brain. It may act on the cord also, but it certainly produces depression of the brain cells. A person asleep from a dose of twenty or thirty grains of chloral does not breathe more slowly than a man in a natural sleep. The brain cells are depressed while the other organs are not notably affected.

The present treatment of tetanus consists in chloral at night only in ordinary hypnotic doses and the bromide of potassium during the day. In poisoning by strychnia, chloral is a very useful remedy, but it is to be given at first only in hypnotic doses.

Dr. Whittaker inquired whether Dr. Nickles had read of more than one case that had succumbed to a dose of less than thirty grains of chloral. Some of us, he said, are accustomed to give thirty grains regularly as a dose. Bouchut does not hesitate to give thirty grains to a child, or even to an infant. Death has occurred from very small doses of morphia, and yet that has not disabused our minds of the idea that a quarter grain is the proper dose of that drug. One or two cases of death from a very small dose of chloral are not sufficient to establish a rule, but if such cases become of frequent occurrence, twenty grains would appear to be the maximum dose. The speaker had always advised the use of chloral only at night; and he had never hesitated to raise his voice against preparations containing both chloral and the bromides.

Dr. Nickles replied that he had not reviewed the statistics for some time, and could recall only one case in which ten grains were followed by death. In his own case thirty-five grains had not produced death, but alarming symptoms took place. He added also that children bear chloral well. Infants may take one or two grains as a rule. He would hesitate to give larger doses to a very young child. He thought that twenty grains should be the maximum initial dose for an adult; he would, however, repeat it in the course of half an hour if necessary, and give a third dose in the course of another hour if the second did not secure the desired effect. If a seemingly healthy patient dies after taking such a dose of chloral, he would not believe that death was the effect of the chloral. In the same way it is an error to attribute the death of a person who has taken an ordinary hypodermic dose of morphia to the remedy, unless a carefully conducted post-mortem fails to reveal any other cause of death.

The speaker added that chloral is not now considered an anodyne, but only a hypnotic. It does not relieve pain as such; however, it may have some action on the sensory nerves when applied locally.

Dr. R. B. Davy agreed with the last speaker in the statement that in most of the cases in which death follows the administration of chloral in ordinary doses the death is the result of some other cause. These deaths, he said, usually occur in individuals who are broken down in constitution, as in drunkards, in whom the action of any remedy is likely to be much modified. With regard to twenty grains as the maximum dose, the speaker had

seen cases in which that dose every two hours would not produce sleep. He then reported a case in which he had prescribed twenty grains of chloral every two hours. At night he was called, and found his patient in a deep sopor, from which she could not be aroused. Suspecting that the condition was not wholly due to the remedy he had prescribed, he ordered an enema, and in a short time after the patient revived from the condition in which he had found her. He also reported a case of convulsions from scarlet fever in which after other remedies had failed he had quieted the spasms by the administration of chloral.

Dr. Reamy, in closing the discussion, said that he had in reporting the case expressed the same doubt entertained by the first speaker, as to whether there was really acute peritonitis present. Of this he had no doubt when the chloral was administered. His doubts had arisen from the promptness and extent of relief obtained. Not only was vomiting relieved, but pain also, followed by sleep, and there was reduction of temperature.

However, he had usually found that when after laparotomy or other surgical operations upon the abdominal or pelvic organs, there is a rise of temperature, and more especially acceleration of pulse, with pain, tympanites, and vomiting, peritonitis is present. He considered under such circumstances, the vomiting of the so-called spinach-colored fluid as almost conclusive. He regarded the elevation of temperature as much less significant than acceleration of pulse. He had seen more than one fatal case of peritonitis where the temperature had at no time been above 101°. In this case the pulse had not been reduced after the chloral was administered, but this was not surprising, as he had in other cases verified the accepted opinion that chloral does not reduce but accelerates the pulse.

The next speaker had probably misunderstood him. He had not recommended chloral as a universal remedy for vomiting, he had not arrayed it against morphine, or placed it above this agent; he had only recommended it in the vomiting of pregnancy, and had inferred from its happy action in the case under consideration that it might prove efficacious in other cases of vomiting dependent upon peritonitis.

The speaker said that he had not the same confidence in the supreme action of morphine in controlling vomiting, as his friend Dr. Whittaker seemed to have. It is well known that in certain subjects vomiting invariably follows upon the administration of morphine, even though it be given hypodermically.

After abdominal surgery, when he has administered morphine for relief of pain and vomiting occurs, he is always, at first, at a loss to know whether it is due to the morphia or to peritonitis, so common is it for morphia to cause vomiting.

With regard to the action of chloral and the method of administration, in reply to the statement of the President that the remedy would have acted as well if it had been given by the mouth instead of by the rectum, the speaker called attention to the fact that the patient vomited everything taken, even a spoonful of water; therefore, the remedy could not have been retained. Moreover, it had been his experience that in the vomiting of pregnancy the remedy acts much more efficiently when administered per rectum.

The speaker had already called attention to the promptness with which chloral is absorbed by the rectum—osmosis commences at once. He would, of course, not pretend that its physiological effects are secured until it has reached the medulla, but he has repeatedly observed, clinically, that so-called after-pains are relieved more promptly and permanently by thirty grains of chloral per rectum, than by the same dose per os; indeed, the relief is more marked under such circumstances than that obtained from one-fourth of a grain of morphia *per os*. He regarded these observations as important.

It is denied that chloral has anodyne properties; in this view he could not fully concur, notwithstanding the highest authority. He supposed it might be considered that opium relieves pain and sleep follows, while chloral secures sleep and relief of pain follows.

THE PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, January 26, 1886.

Dr. H. C. Wood reported

TWO CASES OF SYPHILITIC DISEASE, THE LESION IN ONE INVOLVING THE ASCENDING FRONTAL CONVOLUTION; IN THE OTHER, THE CERVICAL SPINAL CORD.

The first of these cases is of special interest, because so far as the motor symptoms are concerned the situation of the lesion closely agrees with the modern doctrine of cerebral localization, whilst no lesion was found to account for the loss of sensibility. The only explanation that could be given of this is that disease had existed in the membrane over the angular gyrus, and had been removed under the influence of the mercury, there being no record as to the condition of sensation just previous to death. This explanation seems, however, rather lame, because more distinct traces of such lesion would naturally be expected. The cases are also of interest as illustrating a danger which always overhangs a person suffering from syphilitic epilepsy—namely, possible arrest of respiration during the convulsion, and consequent death.

Case I.—R. B., male, aged fifty, entered the Nervous Ward of the Philadelphia Hospital, January 2, 1885. The following extract is taken from the case-books of the institution: "R. B. says that his health has always been good, and whilst acknowledging that he had chancres twenty-five years ago, denies all other forms of venereal disease. Eight years ago he fell downstairs and struck his forehead just above his left eyebrow; he was picked up unconscious, and remained in that condition for four hours. One week after his fall he returned to work, but was troubled with a feeling of lightness in his head and vertigo. About two weeks after this he suddenly felt a peculiar pricking sensation in his right foot, which extended rapidly up the leg to the thigh, and finally to the right arm and thence to the head, and was immediately followed by unconsciousness. He has never bitten his tongue in this or any subsequent attacks. The convulsion was followed by a period of stupor or sleep. About two weeks after there was a second epileptic attack without any aura or other warning. His arm, which had continued in a numb condition ever since his fall, for a time grew steadily worse.

For one year its condition then remained unchanged. He still had epileptic attacks at intervals, varying from a few weeks to a few months. Eighteen months ago he had an apoplectic attack, in which the unconsciousness lasted for several hours. There was no ensuing paralysis; nor did his health seem to be the worse for the sickness. He states that he now has attacks of epilepsy at about monthly intervals. These attacks are preceded by a peculiar twisting of the fingers of the affected hand, and followed by stupor or somnolence, lasting for about twelve hours.

Present Condition: There is partial motor paralysis of the right hand and arm. With the left hand he moves the hand of the dynamometer to 95; with the right only to 30. The æsthesiometer points separated to their widest, are felt on the right hand and arm as only one; on the left arm the points are separated on the ulnar and radial side at two and a half centimetres apart; on the palmar surface at four centimetres. He has not as good use of his left leg as formerly, although there is no complete paralysis of any of its muscles. Patella tendon reflexes normal. Ordered potass. iodide in increasing doses.

Treatment: January 6, 1885. According to statement of nurse, in his fits the patient works altogether with right side. Left pupil slightly smaller than right. Perceptible weakness in right side of face. Dynamometer: right hand, 46, left hand 87. In neither thigh is there any difference in sensitiveness. He complains a good deal of frontal headache. Edges of optic disks sharply cut, and optic disk itself abnormally white, and believed to be atrophic. Ordered to be ptyalized.

The patient was ptyalized, and afterward was given the iodide very freely; but notwithstanding there was distinct improvement in regard to headache and general condition, the fits continued, although at longer intervals, and on the ninth of May there was prolonged unconsciousness after a fit, ending in death.

Autopsy: Contents of thorax normal, except as to congestion; liver is large and congested, indurated, capsule thickened. In the tissue between the right and left lobes, anteriorly and near the lower edge, is a distinct gummatous tumour of the size of a hickory-nut. The new growth has developed from the capsule and grown inward. Upon the upper border of the same fissure and posteriorly is a scar, evidently a healed gumma. Kidneys congested, but otherwise normal. Rest of organs normal.

Brain: When the skull cap was removed some ounces of black blood ran out. Membranes much congested everywhere. Dura mater normal, except in being abnormally adherent to the edges of the great fissure.

Left hemisphere: Arachnoid and pia mater abnormally thick, especially superiorly, and somewhat opaque. Vessels somewhat congested. On external inspection of the bared convolutions nothing abnormal is observed, except about the middle of the ascending frontal convolution, where at a spot one-half inch in diameter the membranes were fused with the brain surface, and could not be separated. The tumor is one-third of an inch in thickness, and in tearing it out a definite cavity was left. No other lesion discoverable in any part of that hemisphere. Remainder of brain normal in general structure.

Cause of death: Œdema of the brain from cerebral syphilis.

Case II.—Cadamoni, aged about twenty-two, entered the wards of the Philadelphia Hospital, June 1, 1885. As he was an Italian of very low order of intelligence, no detailed history of his case could be obtained. He stated, however, that he had been well and strong until three months before, when he had been hurt in the upper part of the back, and had not been able to work since. One month before entrance he had rapidly lost power in both arms.

His condition at the time of entrance to the hospital was as follows: He is unable to stand, and entirely confined to bed, but can make feeble and slow movements of the thighs, legs, and feet; all muscles seeming to be about equally implicated. The whole of the left arm is paralyzed, except the thumb, which can be moved slightly. In the right arm the deltoid and the flexors of the fingers are much wasted. There is no paralysis of the face; patient cannot turn in bed, but has not lost control of the bladder and of the rectum; sensation is not much affected; pain is complained of in the back and side of the neck and in the limbs, especially in the arms; marked pain in the sternal region on coughing. Pressure of the lower cervical vertebræ causes severe pain, and forcible jarring of the head also produces pain in the lower cervical spine; cervical vertebræ not distinctly prominent; patella reflex somewhat exaggerated; temperature normal; bowels persistently very costive.

The patient was put upon a water bed; iodide of potassium given in rapidly increasing doses, until a hundred and eighty grains a day were taken, but the symptoms gradually increased, paralysis became more marked in the lower extremities, and complete in the arms; power over the bladder and rectum was lost, and the patient died June 18th, seventeen days after his entrance into the hospital.

The autopsy was confined to the vertebral tract. In the lower cervical region, extending into upper dorsal, was a thickened mass, several inches long, not at all separable from the membranes of the cord. The outer portion of this is formed of a uniform structureless base, filled with numerous long, narrow, curved cells, evidently derived from connective tissue. Within, this mass is chiefly composed of innumerable small, round, closely packed cells; sometimes arranged in irregular, diffused masses, but in many cases collected into globular masses, which are only in rare instances distinctly separated from surrounding tissue. A few of these masses were yellow, the cells evidently undergoing fatty degeneration, and not taking the stain at all.

Cord underneath the tumor chiefly composed of a structureless, minutely granular, neuroglia matter, with numerous roundish neuroglia cells. No nerve tubule discoverable in section. Gray matter affected nearly as much as white; ganglionic cells still present, although most of them much altered.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, February 3, 1886.

THE PRESIDENT, S. WEIR MITCHELL, M.D., IN THE CHAIR.

DR. THOS. J. MAYS, read a paper

ON THE NUTRITIVE VALUE OF SOME BEEF EXTRACTS: AN EXPERIMENTAL INQUIRY.

A study of the extensive literature of the beef extracts shows the inconstant and indefinite opinions which have

been held concerning their action, and also illustrates the fluctuations of thought which the medical profession is liable to undergo. Liebig, who was one of the first to invest this question with scientific interest, held no less than three different theories regarding their action, during the last twenty years of his life. Since his death, medical opinion has by almost universal consent reverted to the second idea entertained by him, viz., that the beef extracts are of very little or no value as foods. It is true that this has been questioned by some whose clinical observations have led them to different conclusions, yet the works on physiology, therapeutics, or pharmacology, assign the beef extracts among the non-nutritious alimentary agents. Probably the most positive expression of this feeling among those who are considered modern authority on such subjects is that of Dr. Fothergill in his *Handbook of Treatment, or Principles of Therapeutics*, who, on page 537, says that, "as a food, beef-tea ranks low. It contains meat-salts, a small quantity of albumen, and a little gelatine, together with some advanced nitrogenized matters useless in histogenesis. But there is little in it to repair tissues, and less in it to sustain life, so far as our knowledge yet extends. There is little real force-bearing material in the protean compounds of beef-tea. For the starving fever patient, to give him beef-tea alone is almost to give him a stone when he asks for bread. It makes him feel better for the time being, but that is due to its stimulant properties."

There can be no doubt that the cause of the prevailing scepticism concerning the nutritive value of beef extracts is largely due to the experiments which were made by feeding animals exclusively on these preparations, with the result that all of them died within a short period of time. Indeed, Kemmerich affirms that they died more quickly than those which were left to starve from hunger. This has the semblance of proof that beef extracts are not capable of supporting life. Sober reflection teaches, however, that no animal can subsist continuously on any single food, and that such a test would unceremoniously refute the food value of almost any substance, no matter how nutritive it might be. But, beset with difficulties as this investigation evidently is, the question is not whether these substances are capable of sustaining life alone, but whether it can be shown that they contain any nutritive value at all, and if so how much. Here everything depends on the method which is employed to determine this question. It is imperative that this should be definite and exact. It must be able to show the functional state and condition of the organism, before, during, and after the addition of these substances; or, in other words, it must demonstrate whether the organism is, or is not capable of performing work when these substances are added to it.

To meet all these desiderata, Dr. Mays selected the isolated frog's heart.

In summing up the literature upon the action of the frog's heart in its relation to this subject, we find: That the heart in performing work consumes oxygen; that after it is once completely exhausted, it cannot resume its pulsations unless food energy is supplied to it from the outside; that blood, serum, milk, albumen, and gelatine are capable of acting as foods and of restoring its power of contraction, but no other substances have, heretofore, been shown to possess this property; that the pulse elevations and the amount of work which the heart is able to do, depend in a great measure on the degree of concentration of the food. These data, moreover, demonstrate very fully that the heart does not exercise the function of a purely circulatory organ in these experiments, but that it is an organic medium possessed of the power of assimilation, of transformation of energy, of contraction, and of respiration.

The apparatus which was employed in testing the food value of the beef extracts was the following: The heart, by means of a double canula, on which it is securely but gently tied, is attached to a Kronecker-Bowditch heart apparatus, and then through a mercury manometer, and an appropriate glass needle, it records its pulsations upon a revolving cylinder. The heart is fed or transfused through the double canula from two Mariotte's bottles, with any desirable fluid; and in order to keep it pulsating regularly, minimum shocks of one Daniell's cell through a DuBois sliding induction coil, were employed about every four seconds. Before testing the beef extracts, the heart was in every instance well washed out with a 0.6 per cent. saline solution, after which it was allowed to work with the same until all its stored-up material was exhausted and its pulsations reduced to zero. Then a weak solution of the inorganic elements of the beef extracts, chiefly containing phosphate and carbonate of potash, and chloride of sodium, was carefully tested on the heart to find out whether it had any power to induce cardiac contractions, but it failed in every instance. The same was also found to be true of a solution of urea whenever it was tried. After this preliminary work, a number of different dilutions of a beef extract previously prepared with a 0.6 per cent. saline solution (usually in the following proportions—1 : 100; 1 : 250; 1 : 500; 1 : 666; 1 : 1000; 1 : 2000; 1 : 4000) were alternately introduced into the heart and their effects noted. The stronger dilutions, like 1 : 100 to 1 : 500, had no influence whatever in restoring cardiac contractions; but in every specimen which was examined, the dilutions from 1 : 666 to 1 : 2000 had the power of reviving and of maintaining the beats of the heart.

Judging from the data obtained by experiments, the following deductions can be made concerning the influence of the beef extracts on the frog's heart:

1. That they are absorbed and assimilated.

2. That they contain material which has the power of inducing muscular contraction—a power which has heretofore only been shown experimentally to exist in the higher animal albumens or proteids.

3. That, hence, whatever else they may be, they are nutrients in the full implication of that term.

After it was thus demonstrated that these beef preparations contained definite nutritive properties, it was deemed desirable to ascertain the value of each, and means to this end were instituted by comparing their effects with those of a two per cent. solution of dried bullock's blood alternately on the frog's heart in the following manner: In the first place the heart, after being washed out, was filled with the two per cent. blood solution and then allowed to beat until its pulsations were reduced to a minimum, or until the whole nutritive supply of the blood solution was consumed; after which it was washed out again and filled with a solution of the beef preparation to be tested, and allowed to beat with

it until its pulsations were again reduced to a minimum. A large number of comparative tests were made of each of the above named beef preparations in this way, and the following products were obtained, which indicate the mean percentage of the number of pulse beats given by each preparation, while that of blood is taken as 100. These figures are probably not absolutely true, but they give an approximate idea of the nutritive worth of these extracts when compared with that of a two[1] per cent. blood solution, which is capable of producing a normal cardiac contraction.

	Mean Percentage of Number of Pulse-beats.
Liebig's Extract of Beef	58
Johnston's Fluid Beef	59
Valentine's Meat Juice	60
Cibil's Extract of Beef	61
Sarco-peptones (Parke, Davis & Co.)	62
Beef Peptonoids (Reed & Carnrick)	74
Milk	100
Two per cent. solution of dried bullock's blood	100

From this table, it appears that all these preparations contain very nearly the same amount of nutritive material except the Beef Peptonoids, which contain from ten to fifteen per cent. more than the others. It must not be forgotten in this estimation that the Beef Peptonoids are not a pure beef extract like the rest, but a compound of the latter with milk and gluten. Therefore, in order to get at the true value of this preparation it is important to test each ingredient. Milk alone gives as goods results as the blood solution, as can be seen from the table, and there is no doubt that a portion of its valuable property is due to this agent.

The next question which arises in this investigation is as to which of the many organic bodies resident in the beef extracts this nutritive property is due, and principally owing to the difficulty of obtaining these organic extractives, this portion of the work remains incomplete, but Dr. Mays is making preparations to resume it at an early day. It can be safely stated, however, that the inorganic elements of the beef extracts contribute no share to this result, for the phosphate of potash solution contains all these, and in every instance where this was tested it failed to bring out the least cardiac reaction. Hence, these can be left out of consideration.

When finely divided beef muscle is exposed to the action of about four or five times its own weight of cold water for four or five hours and then well pressed out, it loses from sixteen to twenty-four per cent. of its original weight. In this watery solution is contained from two to fourteen per cent. of flesh albumen, while the remainder is made up of kreatin, kreatinin, sarkosin, sarkin, xanthin, carnin, inosit, fat, glycogen, and the inorganic elements; while in the residue there is left nothing but fibrous tissue, principally composed of muscular fibres and connective tisue, which is tasteless, rejected by animals, and entirely unfit for nutrition. Therefore, it is very probable that all the nutritive element of beef muscle resides in its organic extractives.

Now there cannot be the least doubt that the variable amount of albumen contained in the beef extracts furnishes some of the nutritive property displayed by them, but it is far from Dr. Mays's intention to claim that this is exclusively due to it. Indeed, he has found altogether unexpected indications during the investigation which may, on further examination, throw some more light on this question. One thing, however, remains steadfast throughout, and that is, if the albumen of flesh is not the sole nutritive element in these beef preparations, then some or all of the organic bodies which they contain must be nutritious, and can no longer be regarded as effete products of the animal body.

It is not necessary to point out, then, that the multitudinous composition of these extracts makes them a very valuable class of alimentary substances, both for nutritive and constructive purposes. Dr. Mays thinks it is quite evident now that these preparations are assimilated and utilized by the frog's heart without previously passing through a digestive process, and we have no reason for believing that this does not also obtain in the human organism; hence in conditions where the stomach has an intolerance of food, or where there is any hindrance to the introduction of the same through the primary passages, the object of feeding the patient can readily be secured by introducing a suitable preparation hypodermically. A number of years ago he treated several such patients with Valentine's Meat Juice, which, on account of its complete solution in the normal state, is probably preferable for this purpose. He injected from fifteen to twenty minims three times a day with good effects. He failed, however, to keep a record of these cases, but recollected that one was a case of persistent vomiting caused by a severe blow on the head, and that after each injection the patient expressed himself as being stronger and feeling as if he had eaten something. Not the least irritation was produced at the point of injection, and he thinks this field deserves further investigation.

[1] Two per cent. solution of dried bullock's blood gives as good cardiac contractions as fresh blood in proportion of 1 : 3.

NEWS ITEMS.

CANADA.

(From our Special Correspondent.)

Smallpox.—The epidemic has at last burned itself out. The week ending February 12th is the first week without a death from smallpox for about eight months. There are still some sixty cases in the Mount Royal Hospital, but all are doing well. The disease is breaking out in various parts of the province where they have neglected to isolate cases, and where there are no local health boards. The Central Health Board seems powerless to enforce the laws regarding health matters outside of Montreal.

Registration of Births.—A meeting of those interested in the new Public Health Bill was held a few days ago, Dr. R. Palmer Howard in the Chair. A committee was appointed to draw up a suitable bill, and especial directions were given them regarding the introduction of a clause concerning the registration of births. Heretofore the authorities of the Roman Catholic Church have always opposed any registration of births bill, but now they have consented to notify the Registrar of all the baptisms which are performed in their churches. The Protestant clergy have agreed to do the same. Special provision will have to be made for the unbaptized. Although this is rather a roundabout way of getting at

the births, still it is better than no registration. All the Roman Catholics have their children baptized within a week of birth, and there are very few exceptions to this rule. Among the Protestants baptism is not performed so early or so constantly, and a large number do not have their children baptized at all. This class, of course, will be compelled to register before a civil officer. When a record of the births is obtained, compulsory vaccination can easily be enforced.

CALCULUS OF TONSIL.—At a recent meeting of the Montreal Medico-Chirurgical Society, Dr. A. Lapthorn Smith exhibited a calculus of the right tonsil, which he had removed from a young man a few days before. The calculus was as large as a small walnut.

GERMAN GYNECOLOGICAL SOCIETY.—The first Congress of the German Gynecological Society will be held in Munich on the 17th, 18th, and 19th of June, 1886.

IT IS ESTIMATED that fully three-fourths of all the morphine manufactured is used for purposes of self-indulgence in the morphine habit.

TELEPHONES FOR THE SICK CHAMBER.—A London firm has devised a telephone by which persons suffering from contagious disorders may safely communicate with their friends.

MEDICATED OYSTERS.—The *Union Pharmaceutique* for 1885, p. 564, states that, in a perfectly serious advertisement, a French oyster dealer offers for sale both ferruginous oysters and tar oysters.

FERMENTED INFANT FOOD.—Dr. Polden, medical officer, Punjab Northern State Railway, has published an instance of a baby having been intoxicated by a fermented specimen of Mellin's food, purchased in the bazaar. Alcohol was found in the bottle by the Punjab Chemical Examiner.—*Indian Medical Gazette*, Dec. 1885.

MLLE. FRANCELLINE GAROCHE, a native of Nancy, France, has just entered her one hundred and fourth year. Her health is remarkably good, and the Société d'Encouragement has lately presented her with a gold medal. The journal in which this fact is recorded queries whether the medal was for the encouragement of celibacy or for the art of prolonging life.

THE FUTURE OF THE AMERICAN MEDICAL ASSOCIATION.—The meeting of the American Medical Association at St. Louis, Mo., in May next, will be a most important and we trust a successful one. Surely every physician who holds the honor of his profession dear should either go himself or interest himself in sending such representatives as are honorable and pure, free from all selfish motives for self-advancement and preferment and fully alive to the important issues that will be discussed at this meeting. The topic of the International Medical Congress will be the absorbing question for discussion, and will, we hope, be definitely settled, at least so far as it relates to the Association. Of late years this Association has appeared to degenerate into a body merely medico-political and it is time something should be done to elevate it to a proper standard and make it what the British Medical Association is to the profession in England, representative and national. Political intrigue and trickery have too long held sway in this Association and it is time the profession should see to it that it be no longer thus degraded, and be brought back to the place it occupied in its palmiest days. From year to year the meetings have become less and less important in a scientific point of view, and it is time every true physician should individually strive to change its downwward course. If some change is not soon effected, the Association will cease to exist and the profession will turn its attention to the separate special Associations which are all now in a flourishing condition. We hope, therefore, that all who can will make an effort to attend the coming meeting.—*Nashville Journal of Medicine and Surgery*, Feb. 1886.

The American Practitioner (Feb. 20), says: "In spite of all opinions to the contrary, we believe the Association will continue to be the representative body of the great mass of the profession in the United States. It was led astray at New Orleans. It will doubtless be led astray again and yet again, for designing, ambitious, selfish, and industrious plotters will gather at every meeting, and opportunities for their securing power will occasionally occur, and seizing these they will again plunge the Association into errors as unfortunate and as grievous as any of those committed in the past.

"With the lapse of years it will gain experience and grow both soberer and more conservative. It will have done with politics, ethics, and homœopathy. It will make the standing of the individual at home, and the character of his contributions to our common stock of knowledge its single test of loyalty. And, with its eyes cleared of the mists begat by personal feeling, and its heart purified of unworthy ambitions by defeat and mortification, it will come to see that true science knows neither sectional lines nor geographical distinctions, and taking counsel of its toilers rather than of its politicians, of its students rather than of its talkers, of its investigators rather than of its tricksters, it will make itself the accepted apostle of the gospel of work, and enter upon a new era of growth and prosperity."

NOTES AND QUERIES.

THE SENSE OF TASTE: A CORRECTION.

To the Editor of THE MEDICAL NEWS.

SIR: To-day's NEWS reports me as saying at the Neurological Society, in discussing the question of the sense of taste, that "it was considered proper to divide the chorda tympani for tinnitus aurium, and it was supposed to have been done." The very natural mistake of writing "chorda tympani" for *tensor tympani*, is here made. What I said was that, in dividing the tendon of the tensor tympani, the chorda tympani had been, I believed, sometimes divided also, and without perceptible injury to the sense of taste.

Whilst otologists would see that the above was a mistake, yet it might prove misleading to others, and I, therefore, beg a place in your columns for the correction.

LAPAROTOMY IN THE TREATMENT OF PENETRATING WOUNDS AND VISCERAL INJURIES OF THE ABDOMEN.

BY FREDERIC S. DENNIS, M.D.,

PROF. PRINCIPLES AND PRACTICE OF SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; ATTENDING SURGEON TO BELLEVUE, ST. VINCENT, AND NINETY-NINTH STREET RECEPTION HOSPITALS, NEW YORK CITY.

(Concluded from page 230.)

THE *second indication* for laparotomy is in penetrating pistolshot wounds of the abdomen.

The profession in this country is indebted to Dr. W. T. Bull for the first practical application of a new principle in the treatment of penetrating pistolshot wounds. His remarkable case is familiar to all, and a reference to it is made in this connection in order to give to him the credit which he justly deserves.

Lately, in this country and in Europe, there have been several successful cases, which afford valuable evidence as to the propriety of this plan of treatment.

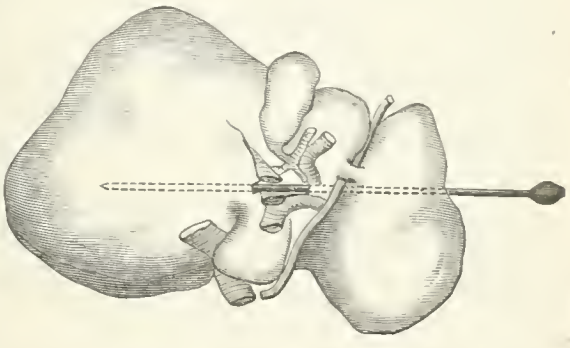
I have recently performed laparotomy in two cases of pistolshot wounds of the abdomen. The histories of these cases are as follows:

CASE XII.—M. R., æt. twenty-three, admitted to the Ninety-ninth Street Hospital, January, 1886. Patient was shot by a policeman with a 32 calibre ball. The wound was situated one inch below the sternum. A Nélaton's probe was introduced very carefully and under continuous irrigation of bichloride of mercury. Patient was in shock, and the fact that the bullet had entered the abdominal cavity led me to believe that the only chance of recovery was to open the peritoneal cavity. The median incision was made and the contents of the cavity carefully examined, wrapping each section of the intestine in towels wrung out with a warm solution of bichloride of mercury. During the examination a tremendous gush of blood appeared, and upon introducing my hand, thoroughly disinfected, at the time, into the bottom of the cavity. I felt a wound upon the under surface of the liver and my finger entered the transverse fissure. This was the source of the hemorrhage, and I mentioned this fact at the time to Dr. Messemer, the Coroner, and stated that the hemorrhage proceeded from the large veins in the transverse fissure. The hemorrhage filled the peritoneal cavity, which was cleansed of clots. There was no perforation of the intestine. The patient sank rapidly, and was almost pulseless. The wound was closed, the hemorrhage arrested by pressure as far as possible and stimulants administered.

The patient rallied a little, and finding his pulse very feeble I determined upon transfusion through the radial artery, which upon being completely divided did not bleed. The saline solution of Mikulicz was employed, which consisted of one litre of warm distilled water, in which were dissolved six grammes of chloride of sodium and one gramme of carbonate of sodium. Twelve ounces of this solution were transfused into the radial artery toward the heart, with marked effect. His pulse was, a few minutes after the transfusion, 130 per minute, and the patient seemed to rally. The canula was retained in the artery, and every four hours a fresh transfusion was made. His condition was greatly improved by the transfusion, and I began to feel that some hope might be indulged in as to his ultimate recovery, similar to another case of mine in which transfusion was employed in a secondary hemorrhage following a gunshot wound of the jaw, and in which recovery took place. In forty-eight hours after the operation, the patient died.

Autopsy made by Dr. Grauer in the presence of the coroners, January 5, 1886. Brain showed evidences of chronic meningitis as a result of alcoholism. The lungs were œdematous. The intestine *was not wounded*. The bullet entered the upper surface of the left lobe of the liver, and the track of the bullet as followed by a probe was downward and to the right. It traversed

FIG. 4.



Dotted line shows track of bullet, wounding vessels in transverse fissure; ball lodged in right lobe.

the transverse fissure of the liver and wounded the portal vein and other vessels in its passage through the substance of the liver. The bullet was found by Dr. Herold lodged in the lower part of the right lobe of the liver. There were evidences of the beginning of peritonitis and hepatitis, and many veins were also wounded in the liver tissue. There was some blood in the peritoneal cavity.

The remarks which I would offer in this case of pistolshot wound of the liver are these:

First. That while laparotomy did not save the patient, the operation did not hasten death; but prolonged life by temporarily arresting the hemorrhage.

Second. The diagnosis of the injury was made certain by the laparotomy, and while it was utterly impossible to expect a recovery under these conditions, the precise nature of the injury was diagnosticated, and the treatment was directed accordingly.

Third. The wound was a mortal one. There is no case which has ever recovered where the bullet passed through the centre of the liver, wounding small vessels in its substance, and large venous

trunks in the transverse fissure. Every surgeon knows how extremely fatal even peripheral injuries of the liver are, and how few have ever recovered. None have recovered with a central injury, which destroyed vessels in the interior of the organ and large veins in the fissure. It is impossible to believe that any injury involving the large vessels in the liver could be anything but an absolutely mortal wound.

Case XIII.—Mrs. K. B., æt. twenty-six, admitted to Ninety-ninth Street Hospital, Jan. 10, 1886, suffering from pistolshot wound of abdomen. The ball, which was a 32 calibre (Colt's revolver), entered half an inch to the left of the umbilicus. Upon admission the patient was not in profound shock. Temp. 100°, pulse 112, resp. 24, and suffering but little pain in abdomen; pain is increased during deep inspiration. There was loss of hepatic flatness over region of liver. The urine contained no blood and was clear and normal. I proceeded at once to perform a laparotomy and the peritoneal cavity was opened, and there was present fecal extravasation. Seven openings were found, which were carefully sutured by the Lembert stitch, and one perforating wound of the mesentery. The abdominal cavity was filled with venous blood, and the hemorrhage from the deep-seated venous trunks was appalling. The amount of hemorrhage became so large and alarming and entirely beyond control, that it was thought expedient not to continue, in view of the fact that the patient was almost pulseless at the wrist and was evidently dying. The intestine was replaced, and its weight seemed to control the hemorrhage for the time. The abdomen was closed, and the patient contrary to expectation rallied, and by stimulation at intervals of every few minutes lived for about forty-eight hours.

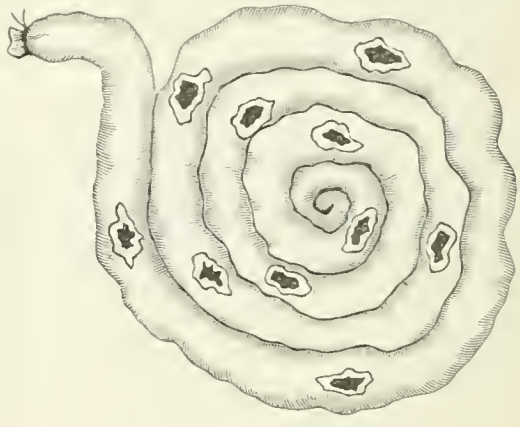
Autopsy. The seven openings were tightly closed by the sutures and no perforation in the gut had been overlooked. These wounds were water-tight. The bullet wounded the iliac veins and was found lodged in the psoas muscle in the vicinity of the promontory of the sacrum. The cavity of the abdomen was filled with blood.

Laparotomy in this case discovered the seven large perforations in the intestine. These were securely sutured, and no openings were overlooked. The operation also enabled the surgeon to remove the fecal matter from the peritoneal cavity. Thus far, the value of the operation is unquestioned; but the laparotomy did not render the arrest of the hemorrhage possible. Sponges and towels were simply buried in a pool of venous blood, the source of which could not be traced, owing to the repeated gushes of blood, which welled up from the pelvic cavity in a continuous and rapid stream. The bleeding veins could not be discovered, so rapid and great was the flow of blood from them. It seems to me, the great thing to be learned in laparotomy is a method of arresting the hemorrhage from such vessels as the vena cava, iliac veins, and the portal veins, and when this object is attained laparotomy will be attended with almost uniform and brilliant results.

It is fortunate that wounds of the large venous trunks seldom complicate the other visceral injuries. It was my misfortune to meet with two of these cases. The attention of the profession should be directed to this one point, and when a sure method is found which will control hemorrhage from the large veins, laparotomy, as an operation, will meet with unparalleled success. It would seem that some sort of mechanical pressure upon the vessels above near the diaphragm, and a tourniquet around each thigh, would save enough blood to prevent the patient from being exsanguinated while an attempt was made to secure the wounded veins down in the bottom of the peritoneal cavity. Until one has witnessed a hemorrhage such as I have described, he cannot appreciate the difficulties of the task, and in the future I shall endeavor to have in readiness some device to check temporarily such a hemorrhage, and some one whose entire attention is to be centred upon this one point during the operation. It is absolutely impossible to find a large venous trunk which is actually bleeding from the bottom of the peritoneal cavity and behind the peritoneum, unless some means is devised to arrest for a few seconds the torrents of blood which well up with such rapidity as to be in no way controlled by sponges or towels. Before the sponge can touch the spinal column to make pressure upon a large vein, the sponge is soaked with blood, and the hand is entirely buried out of sight in a pool of constantly rising blood, until the hemorrhage overflows the sides of the incision into the walls of the abdomen. Mechanical pressure, directly applied upon the vertebral column to arrest any arterial hemorrhage from the many branches of the aorta, and the application of a tourniquet to both thighs, may possibly control the bleeding sufficiently for a few moments until the surgeon can find the bleeding venous and arterial vessels.

Case XIV.—J. McA., admitted to Bellevue Hospital September 26, 1885, was accidentally shot. Upon his admission that same day at 2 P. M., patient was almost pulseless, cold and pale. Stimulants were employed,

Fig. 5.



The ileum, showing ten perforations.

and patient, at 5 P. M., had a fairly good pulse; skin moist; pain less. In the evening, pulse 130, temperature 102° F., and abdomen slightly tympanitic. At 10 P. M. patient's condition slightly improved. Sept. 27 patient's condition still better, and his condition remained so until late in the evening, when pulse became very feeble and rapid, tympanites increased, hepatic

flatness lost, and friction, fremitus, and murmur could be heard over liver. Patient sank rapidly during the evening, and expired about midnight.

Autopsy. Made by Dr. Pinkerton. Wound was situated one inch to the right of the external border of right rectus muscle, and opposite to a point on a level with the anterior superior spinous process. Peritoneal cavity filled with gas; the intestine was congested, agglutinated with lymph, and there was a quart of bloody serum in the cavity. No fecal extravasation was found. There were ten perforations, which were observed in three distinct groups, each group occupying about ten inches of intestine. The gut was contused and ecchymotic about the wounds, and the mesentery was injured at several points. The bullet had perforated the mesentery at one place only, and was found in the tissues between the rectum and the promontory of the sacrum, a little to the left of the median line.

The remarks that seem pertinent in reflecting upon this case of penetrating pistolshot wound of the abdomen, in which there were ten wounds of the intestine, are these:

First. Failure to perform a laparotomy deprived the patient of the only possible chance of recovery.

Second. If laparotomy had been performed, it is reasonable to believe that life might have been saved, because no fecal extravasation had occurred into the cavity, though it was filled with gas, and because no hemorrhage had occurred.

Third. Absence of positive symptoms of wound of intestine until shortly before death led to error as to the precise nature, extent, and character of the injury.

Fourth. Symptoms cannot be relied upon as an unerring guide in diagnosis. They may be almost entirely absent, and yet many perforations exist.

Fifth. The continual improvement in the patient up to within a few hours of death was misleading in this case.

Sixth. Since negative symptoms will not exclude injury of the viscera, the exploratory laparotomy in doubtful cases is justifiable on the ground that the operation is performed with little additional risk, and a failure to do so may result in death.

Seventh. The light thrown upon this subject, from a study of this particular case and of others, led me to a conviction of the right of the surgeon to interfere by laparotomy.

A case which I saw, and which was under the care of Dr. Charles Phelps, the history of which has been kindly prepared for me by Dr. Conway, the House Surgeon in Bellevue Hospital, illustrates the danger of refusing to operate.

CASE XV.—C. C., æt. twenty-five, admitted to Bellevue Hospital September 9, 1884. Patient was shot by her husband. After the shooting she was able to walk into an adjoining room. Upon admission patient was in great shock, and a bullet wound was discovered near the umbilicus. Stimulants and morphia were administered and the wound dressed antiseptically. The patient developed peritonitis, and died in about seventy-two hours.

Autopsy. The bullet had wounded the sigmoid flexure, and was flattened by striking the bone. The bullet then dropped into the pelvis. The cavity of the peritoneum contained gas and feces, and the membrane itself shown signs of acute peritonitis. There were only two small openings in the gut made by a bullet (22 calibre).

This case is another one which illustrates the value of laparotomy. In the absence of any hemorrhage the two perforations could have been easily discovered and closed, the peritoneal cavity sponged out, and the median incision sutured.

The following surgeons have published successful cases of penetrating pistolshot wounds where either a true laparotomy was performed or the original wound was enlarged, the perforations sutured and the cavity sponged:

Kocher,	(stomach)—recovery	1
Bull,	one case "	1
Ramsay,	" " "	1
Legouest,	two cases—recoveries	2
Hamilton,	one case—recovery	1
Smartt,	" " "	1
	Total	7

There are, of course, other cases, but these seven cases have been found in recent medical journals. The list does not include my two cases, because they were both fatal from hemorrhage. I have omitted to mention those cases in the above list where a laparotomy was performed and the cases terminated fatally, because so few are published and so great a number remain unpublished, and hence no data could be established which would in any way give a proper ratio between the recoveries and the deaths. All the recoveries are reported, few of the fatal cases are reported, and hence time must elapse before a proper estimate can be made. It will not be long before surgeons will be induced to contribute all their cases, and when we have before us all the successful and unsuccessful cases the mortality of the operation can be correctly estimated. It is sufficient for the present to ascertain whether any successful cases can be presented, because all of these patients are necessarily mortally wounded if penetration and perforation have taken place. As the technique of the operation is better understood, and the methods of controlling hemorrhage are studied, as the signs and symptoms of perforation are made more reliable guides, the death-rate after laparotomy will be greatly diminished. Dr. Otis states that it may be still considered doubtful if an incontestable instance of recovery was observed in penetrating gunshot wounds. With such a deplorable condition as this, certainly laparotomy, if it saves only one life in many, all of which are doomed to inevitable death, is a justifiable procedure.

The *third indication for laparotomy* is where there is a rupture of the intestine. This condition is the result of traumatism.

The rupture of the intestine due to pathological processes, as in strangulation or ulceration, will not be considered this evening.

Rupture of the intestine from traumatism can be best studied and investigated by an examination of these many pathological specimens, a most interesting set of which I have been able to collect. The indication can also be studied by a reference to the clinical history of some cases which I shall present. The great difficulty which naturally con-

fronts the surgeon is the absence of a positive diagnosis. So many other conditions simulate the symptoms of rupture of intestine that the surgeon must be exceedingly careful in the conclusions at which he arrives before performing a laparotomy.

Case XVI.—K. F., æt. eleven years. September 18, 1883. This specimen, which was taken from the

Fig. 6.

Rupture of duodenum near junction of jejunum.

abdominal cavity, illustrates the indication for laparotomy in cases of rupture of the intestine. The child was run over by a cart, the wheel of which passed over the anterior wall of the abdomen. Death occurred in twenty-four hours after accident.

Autopsy showed beginning fibrino-purulent exudation on peritoneum and about eighty ounces of yellowish-brown fluid in the peritoneal sac. No gas in the peritoneal sac. The retroperitoneal tissue was markedly emphysematous, especially behind the cæcum and the ascending colon, around the urinary bladder, and near the duodeno-jejunal junction. At the last mentioned place a soft yellowish material like feces was present in the areolar tissue. There was perforation of the middle portion of the duodenum. Other organs normal. The col-

Fig. 7.

Rupture of small intestine.

lapse, rapid respirations, and frequent pulse, vomiting, and, above all, emphysema, which was distinctly felt behind, denoted rupture of the intestine.

Laparotomy in this case might have saved the life of the patient. The diagnosis was made before death, which diagnosis was proved correct by the autopsy, and the failure to do an abdominal section on my part in this case illustrates the important lesson that an opportunity was lost to save a human life, where perhaps it might have been saved by abdominal section.

Case XVII.—J. O. R., æt. seventeen, admitted to Bellevue Hospital, Oct. 3, 1883. Patient was run over by a wagon, the wheels of which passed over his body. No external evidence of injury save two slight bruises. Patient is in considerable shock.

Autopsy. The peritoneal cavity, upon being opened, showed a rupture of the duodenum and the specimen was sent to the Wood Museum. There is no regular report of the autopsy; but a note attached to the specimen states that there was also injury to right kidney.

This is another case where an exploratory laparotomy might have saved life; but the operation under these conditions was not considered at the time a recognized one in surgery.

Case XVIII.—This specimen was taken from the body of a person who had been struck by a street car. There is a rupture of the serous or external and the mus-

Fig. 8.

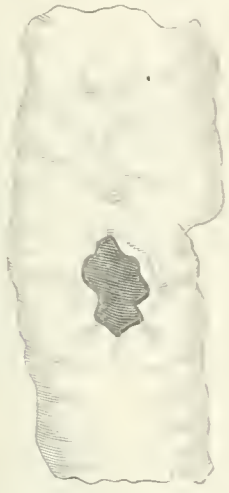
Rupture of serous and muscular coats.

cular or middle coats of the intestine; but the mucous coat is not ruptured. It protrudes through the rent in the two outer coats and forms a hernia of the mucous coat. This hernial protrusion is more or less constricted and forms a pouch or diverticulum. There was no external wound upon the abdominal wall. There was considerable retroperitoneal hemorrhage. Patient lived twenty-four hours after accident. There is no clinical history attached to the specimen except such as has been given.

Laparotomy might have saved this life, by arresting the hemorrhage, which seems to have been the cause of death. The hernia of the internal coat could have also been operated upon and cured.

Case XIX.—P. W., æt. forty-two, admitted to St. Vincent's, Nov. 1885. Patient, while engaged in a sparring match, was struck by his opponent's fist. Pa-

Fig. 9.



Rupture of small intestine by fist.

tient was brought to hospital in condition of moderate shock. He complained of severe fixed pain in abdomen. There was no external evidence of injury. The following day pain diminished in intensity; but the pulse was more rapid and smaller. In the evening pain was severe and fixed. Passed a restless night and died in collapse the next day.

Autopsy. Upon opening the abdomen there was extravasation of blood in the planes of muscles; but no ecchymosis apparent externally. Liver and intestine were studded with lymph and were very much congested. There was seen a rupture of the ileum about two feet from the ileo-cæcal valve. The rupture was large enough to admit the end of the finger. The edges of the wound were everted and a mass of fecal matter protruded through the opening.

Laparotomy in this case might have saved the life of the patient: at all events, the only chance for recovery was a laparotomy.

Case XX.—C. R., admitted to Ninety-ninth Street Hospital, December, 1883. Patient was struck by a pole of a truck. No external signs of injury. Patient was in shock upon admittance and his condition grew rapidly worse until his death, which occurred about forty-eight hours after injury.

Autopsy. A rupture of the ileum was found and peritonitis. There was no extravasation of fecal matter, but gas was contained in the peritoneal cavity.

In the absence of any hemorrhage and fecal extravasation, a laparotomy early performed might have saved the life of this patient; because he died from peritonitis caused by the rupture of the intestine.

Case XXI.—W. L., æt. twenty-eight, admitted to Bellevue Hospital, Jan. 16, 1882. Through the courtesy of Prof. Wright the following facts were obtained from the clinical register. Patient had simple fracture of tibia and fibula of both legs and severe pain in the right iliac region, and was in a state of profound shock. During the night the patient partially reacted, and on the following morning temp. 97 1/2° F., resp. 28, pulse very rapid and feeble. During the day patient had a movement from the bowels, but was unable to urinate. At 4.45 P. M., Jan. 17th, patient died.

Autopsy. When peritoneum was opened gas escaped from the cavity and fecal extravasation was present. The jejunum was ruptured four inches from its com-

Fig. 10

Rupture of intestine.

mencement. Perforation large enough to admit the finger, and the opening was opposite to the mesenteric attachment. Evidence of commencing general peritonitis, the membrane hyperæmic, and spotted with shreds of lymph.

If laparotomy had been performed at once in this case, it is not unreasonable to believe that the life might have been saved.

I have searched through many journals in English, French, and German, to find a case where laparotomy was performed for the relief of rupture of the intestine which occurred as the result of traumatism. The following case is the only one that could be found to meet precisely these conditions, and illustrates the necessity for the operation under these circumstances. Horsley, Mikulicz, Wiltshire, Treves, Andrews, and Marsh have performed laparotomy, and with success, in acute septic peritonitis: but I do not know of a single case where a successful laparotomy has been performed for rupture of the intestine which has been produced by traumatism, and only one case in which laparotomy was performed under these circumstances.

Case XXII.—Mr. Owens, of London, reports in *Lancet*, vol. ii. p. 663, 1885, a case where a patient sustained a rupture of the intestine from a plank falling upon the abdomen. There was no external injury. Patient had many of the signs and symptoms of perforation, and exploratory laparotomy was performed. The perforation was discovered, the opening sutured, and the viscera returned. The patient, however, died.

This case is a most important contribution to the meagre literature of this subject. Laparotomy was indicated, and it is to be regretted that the patient did not recover. The surgeon afforded the patient the only chance to recover.

Let me now refer to some cases which I have found in my researches upon this point, to illustrate from a clinical point of view the necessity for laparotomy in case of rupture of the intestine, but where the operation was not performed.

Case XXIII.—Dr. Perier reported a case of rupture of the intestine in *Le Progrès Médical*, January 26, 1884. The patient was run over by a carriage, the wheels of which passed over his abdomen. The patient was in marked collapse upon admittance, and died the following day.

Autopsy. The peritoneal cavity contained about two litres of blood, but no blood-clots. No traces of peritonitis. The intestine was found completely divided, and the retroperitoneal space was filled with bloody serum.

The points of interest in this case, Dr. Perier states, are the absence of any external violence upon the abdominal wall, associated with the fact of a complete section of the gut; also the absence of peritonitis with a rupture of the intestine. The cause of death was from internal hemorrhage instead of peritonitis; as is the rule in such cases, the hemorrhage was from a branch upon the anterior part of the aorta, and the blood extravasating posteriorly; laparotomy might have saved this patient's life. The gut could have been sutured, and in the absence of peritonitis the condition would justify the conclusion that laparotomy might have saved life.

Case XXIV.—Dr. Duplay reports also a case of rupture of the intestine in *Le Progrès Médical*, November 15, 1884. The patient was run away with, and it was supposed the carriage passed over his abdomen. Patient was in collapse, and died the same night.

Autopsy. The peritoneal cavity contained about two litres of blood, which escaped from a wound in the inferior mesenteric artery. The intestine was completely divided.

The reflections which Dr. Duplay makes upon this case are, that the absence of fecal extravasation in a case of complete rupture of the intestine is exceptional. He explains this fact by a reference to Jobert's experiments upon dogs, in which he showed that if the intestine be completely divided, the ends may contract by their circular fibres, and thus prevent extravasation; that feculent odor to the extravasated blood is explained by the phenomenon of endosmosis; that any hemorrhage, except, perhaps, from the aorta or the vena cava, ought to be controlled by a laparotomy. In this case a laparotomy might have saved the life of the patient, whereas a failure to perform this operation deprives the patient of the only chance of recovery.

Before dismissing this subject I wish to report a case which occurred to me last autumn, illustrating the uncertainty of the diagnosis of rupture of the intestine from collapse and tympanites.

Case XXV.—A. N., æt. thirty-five, admitted October 17, 1885, to Bellevue Hospital. Patient fell while attempting to climb into an upper berth on a steamer. She states that in her fall her side and abdomen struck upon the edge of the stool upon which she was standing. Upon admission patient's abdomen was distended, slightly tympanitic, and the slightest pressure upon the abdomen produced very severe pain. Respirations were rapid and thoracic in character. Pressure over the part struck was attended with excruciating pain. Pulse hard, wiry, and rapid. Constipation had existed previous to accident for several days. Temperature 100° F.; knees flexed. Patient was very nervous and excited; no vomiting. General peritonitis developed. A fracture of the last rib was discovered, which had produced the peritonitis. The opium treatment was carried out, and in twelve days the patient recovered.

The general signs and symptoms of peritonitis in this case, taken in connection with an injury, the nature of which has been shown to produce rupture of intestine, were strong evidences in favor of rupture of the gut. It is to be noted, however, that emphysema was absent, also hepatic flatness was not lost, and these two important signs were necessary to make a positive diagnosis. This case is mentioned in order to emphasize these two pathognomonic signs, and also to place the surgeon upon his guard, lest mere collapse with general peritonitis following a traumatism, may lead to error in diagnosis and treatment.

Case XXVI.—Dr. Hartigan reported a case of rupture of the ileum in the *Journal of the American Medical Association*. The specimen was taken from the body of a man who had been kicked in the abdomen. There were no external signs of injury. The patient died two days after the injury, and the autopsy showed signs of peritonitis produced by fecal extravasation.

This is another typical case where laparotomy would have afforded the patient his only chance of recovery, and there is every reason to believe that this operation would have been attended with success on account of the absence of hemorrhage and of only a single wound to suture.

The general conclusions which can be deduced from a study of the clinical and pathological facts thus presented in these cases of rupture of the intestine are these:

First. Clinically, emphysema is the only reliable sign of rupture of intestine, and collapse is the constant symptom with but a very few exceptions. But as collapse is present under so many other different conditions this symptom is not pathognomonic and loses its diagnostic value.

Second. Pathologically, the seat of the rupture is always in the small intestine, and this renders the operation less difficult than when the large intestine is involved.

Third. The sudden contraction of the circular muscular fibres of the middle coat of the intestines usually closes the opening in the distal and proximal ends of the gut, and thus prevents fecal extravasation into the peritoneal cavity, and this condition renders the prognosis more favorable than where rupture of the intestine follows ulcerative processes: because no peritonitis exists before the perforation, and in some cases no peritonitis follows the perforation. Death, in these cases, has been caused by hemorrhage and shock. Small hemorrhages are ar-

rested by the circular and longitudinal contractions, which, it has been demonstrated, prevent fecal extravasation.

Fourth. The mechanism of rupture of the intestine is somewhat obscure. It is probably caused, as Gendron and Ollive have pointed out, by the distended small intestine being pressed upon the vertebræ by a force acting in front and directed backward. By this mechanism there is a compression of the tympanitic gut between the force inflicting the blow anteriorly and the lumbar vertebræ posteriorly.

These ten cases of rupture of intestine are most interesting, because they illustrate an indication for laparotomy in visceral injuries, which operation has only been once performed, and then unsuccessfully. This injury opens another new field for inquiry and research, and enlarges the domain of abdominal surgery by adding another condition in which laparotomy should be performed, and without which the patient cannot survive. This triumph in abdominal surgery remains yet to be accomplished, and the first successful case will be eagerly looked for by the entire medical profession.

The *diagnosis* of injury to the abdominal viscera is a most important subject of study. With the exception of two signs, the diagnosis is to be arrived at by a study of the group of symptoms, any single one may be corroborative; but all of which, taken collectively, afford sufficiently positive evidence of injury to justify a surgeon in performing a laparotomy. The extravasation of the contents of the intestine in the wound, and the presence of emphysema in the adjacent tissues, may be said to be pathognomonic. There is, however, in addition to extravasation and emphysema, a chain of symptoms which has an important influence upon the subject of diagnosis.

Extravasation of fecal matter. This is a positive sign and admits of no exception. Whenever fecal matter is seen at the wound, it is proof that the intestine has been wounded. If the extravasation takes place within the peritoneal cavity, this sign is of no value until the abdominal cavity is explored.

Emphysema of tissues. This sign is also a positive one, and consists of the escape of gas from the intestine into the surrounding tissues, especially into the retroperitoneal, cellular, and connective tissue. This condition must not be confounded with an emphysema incident to an injury of the lung, which gives rise to the presence of air under the skin, and which might coexist with a penetrating abdominal wound, or from emphysema a result of gangrene of tissue from gas. In a penetrating stab or gunshot wound, emphysematous crackling is pathognomonic of perforation of the gut. I have seen this condition present in two cases of penetrating wound, and attach very great importance to the presence of this sign as evidence of a perforation of the gut.

Shock. The amount of shock depends more upon the idiosyncrasy of the individual than upon the actual injury to the intestine or organs. The persistency of the shock is of greater diagnostic value than its severity. I had one patient who had ten perforations in his intestine, and he lived nearly forty hours, and up to within four hours of death had no shock that could not be explained by an ordinary surgical injury. There was nothing at the outset that indicated perforation. The intestine is here upon the table, and it is a specimen which is of great value, taken in connection with the clinical history, because it demonstrates that it is possible not only to have one but a great many perforations of the intestine, and yet no shock be present sufficient to explain the condition. Absence of shock will not always exclude injury to the viscera; its presence, however, if persistent, is a strong link in the chain of evidence.

The question of shock as a symptom in penetrating wounds of the abdomen, is most important. My experience in many such cases has led me to believe that the shock is more apparent than real. This symptom in penetrating wounds is, to my mind, analogous to that observed in strangulated hernia. Both symptoms are manifestations of a depression of the sympathetic nervous system, and not the cerebro-spinal. No surgeon would hesitate to operate for the relief of a strangulated hernia because great shock was present. But in strangulated hernia the shock is due to a pressure upon the sympathetic nerves and ganglia which preside over the involuntary muscles of the alimentary canal. The shock is at once removed after the stricture is divided, and the patient's condition is immediately improved. In nearly fifty cases of strangulated hernia of which I have notes, and many of which have been sent to me through the kindness of Dr. Knight, of the Hospital for the Ruptured and Crippled, there are only three cases that I can find, where the patient died during or immediately after the operation. The shock in most of these fifty cases was as severe as in any case of stab or gunshot wound of the abdomen that I have seen. This condition of shock is precisely the same in the penetrating wounds, and I cannot find a case (excluding the three) in which the condition of the patient was not improved after the operation.

I do not mean to undervalue the symptom of shock; but I believe it is more apparent than real, and that its presence, even to a considerable degree, should not deter the conscientious surgeon from beginning a laparotomy. I feel sure that most of the cases in my list of penetrating wounds were improved, as regards the collapse, as soon as the peritoneal cavity was opened.

The shock in abdominal surgery was forcibly impressed upon my mind by a case which occurred in Langenbeck's clinic, in the winter of 1876. A case of strangulated hernia was admitted to the clinic in a moribund condition; Langenbeck operated and the patient expired upon the operating table. I remember well the remarks which this renowned surgeon made, as well as those in connection with this subject in his lectures upon military surgery. He said that he had seen patients almost pulseless with a strangulated hernia, and reaction follow after division of the stricture, and recovery take place. He said, further, that in these cases it is the duty of the surgeon to operate; because a patient may rally though moribund at the time, and the opera-

tion itself is the only possibly chance of recovery. The collapse is always greatest in an acute case of strangulation, when the hernia has appeared for the first time, and the analogy is observed in penetrating wounds. In old hernia the shock is never so severe.

Following the teaching of this great surgeon, under whose instruction it was my privilege to be for nearly two years, I feel that I have saved several lives which might be said to have been almost hopeless. Out of a number of cases operated upon for relief of stranulated hernia, where the patients were in extreme collapse, some have lived because herniotomy was performed, even though the shock was very profound. The same principle holds good in penetrating wounds, and the operation of laparotomy should be employed irrespective of shock, which is of a peculiar nature, is deceptive as to its severity, and offers no tangible excuse for a surgeon to decline the operation because he may think his patient will die upon the table.

The shock in those cases where there is no wound of the viscera, can, perhaps, be explained by the anatomical connection between the last seven dorsal nerves, which preside over the movements of the abdominal walls, and the splanchnic nerves, which are derived in great part from these dorsal nerves. For example, the effect of such stimulation upon Auerbach's plexus, which is supposed to control the peristaltic action of the intestine, is to produce a marked depression of the sympathetic system, and consequently the shock appears greater than it really is.

Thus, it is obvious that the presence or absence of shock affords no information to the surgeon as to direct injury of the intestine. There is one case reported by Taylor, where the duodenum was torn across, and the boy walked a mile and died in thirteen hours. Another case is reported by Poland, where a man, after a rupture of the intestine, experienced so little shock that he walked to his bed and undressed himself. Key reports a case where a man continued to carry sacks of flour to a vessel after rupture of the intestine. Agnew relates still another case, where a patient was able to wheel a cart across the yard. In one case which I had, there were several openings in the gut, and little or no shock present.

The shock, then, may be present immediately, and death supervene within an hour, or it may be deferred for hours—in the meantime the patient walks about the room; or shock may be absent for a day or two, and then the patient die in sudden collapse.

Tympanitic resonance over liver. This is a most important physical sign. It cannot be relied upon, however, as positive evidence of perforation. Liver flatness may be absent, and a tympanitic resonance be present, and yet other conditions than perforation may have brought about this change. Sudden distention of the colon, which may force the anterior border of the liver upward against the anterior wall of the chest, will, according to Prof. Janeway, cause the percussion note to be tympanitic over the normal area of liver flatness. In this event the liver flatness is posteriorly greater than normal, provided that there is no marked emphysema of the lungs.

Persistence of liver dulness, or flatness on percussion, Prof. Flint regards as of much importance as evidence against perforation. He has found that the injection of a small quantity of air into the peritoneal cavity in the cadaver causes the hepatic dulness or flatness over the liver to disappear, a tympanitic resonance taking its place. Clinical observations have shown that gas escaping from an intestinal perforation gives rise to a tympanitic resonance in the hepatic region. A tympanitic resonance in this region, however, is not proof of the presence of air or gas in the peritoneal cavity, inasmuch as this resonance may be caused by the transmission of resonance from the colon above the lower margin of the liver. But, if dulness or flatness over the liver persists, it may be concluded with positiveness that the peritoneal cavity is free from air or gas.

Dr. Biggs has called attention to two important facts: that adhesion of the intestines to the anterior abdominal wall may give rise to tympanites, or that a previous hepatitis may result in adhesion of the peritoneal covering of the liver to the abdominal wall, and thus prevent the escape of gas over the liver area. These are valuable observations to bear in mind.

Sudden meteorism. This is another symptom which is of great value as a diagnostic sign. It is difficult to differentiate this condition, which may be caused by a perforation from the tympanites following acute peritonitis, which may develop in a few hours. It is the suddenness of the meteorism, as well as its persistency, which must be taken into consideration. It must be observed that sudden tympanites may result also from a blow upon or injury to the abdomen or spinal cord. This condition of tympanites is due to a paralysis of the muscular coats of the intestine, and must not be mistaken for tympanites over the liver, the result of perforation.

Subnormal temperature. This symptom is generally present before peritonitis is developed, owing to the condition of collapse or shock in which the patient is usually found.

The *pulse* is rapid and feeble, and this sign is of great value. I have seen, in one case, the only thing pointing to a serious lesion in a penetrating wound was the great rapidity of the pulse and its feebleness. These characteristics of the pulse may be present in other injuries, but no serious lesion of the viscera can occur without a disturbance of the character of the pulse.

Fixed pain distinctly located. This is also a valuable symptom taken in connection with others, but is of no value by itself. I have seen, lately, this symptom present to a marked degree in a case of strangulated hernia which had been reduced by taxis, and I suspected a continuance of the trouble which it was hoped was relieved by the taxis. The pain was intense, and was localized and persistent; but, after twenty-four hours, subsided under the influence of morphia, and the patient recovered.

Vomiting. A symptom usually present in penetrating wounds, but one which is also present under so many other conditions that its value is only to be estimated in connection with the train of symptoms. Its absence will not exclude perforation; its presence is only corroborative proof.

Bloody stools. A most valuable sign in perforation, but one seldom seen, as peristalsis seems to be suddenly arrested for a time in the alimentary canal below the seat of injury. I have never seen this symptom, but I find it described by others, and should place great reliance upon its presence.

Retention of urine. This symptom varies, and to its presence no special importance can be attached. I have felt the bladder distended until it reached nearly to the umbilicus, and the patient was unconscious of the fact. The physician assured me that he had only just passed the catheter. A search should be made for albumen and for indican in cases where there is supposed perforation; the same as should be done in strangulation.

Anxious physiognomy is generally present in these visceral wounds, and the patient is extremely nervous. The patient's face is similar to that seen in cases of strangulated hernia or cholera.

The *respirations* are rapid and shallow, and for the most part thoracic. The muscles presiding over abdominal respirations are quiescent.

Acute peritonitis develops very soon after perforation or any visceral lesion. It may take only a few hours to develop. Its presence is, of course, most discouraging. As a symptom of perforation, the development of acute peritonitis is most significant.

Technique of the operation. In laparotomy every detail must be conscientiously observed. The success depends upon the manner in which the minutest detail is carried out during this formidable operation. The operating-room should be thoroughly disinfected with burning sulphur, which should be placed near the ceiling, and as the gas descends the room can be properly disinfected. The pan of sulphur should never be placed upon the floor, because the vapor will not ascend and such disinfection is useless. The temperature should be high, and kept so during the entire operation.

All known stimulants should be in readiness for immediate use, including the transfusion apparatus with Mikulicz's solution prepared as already mentioned.

The patient's abdomen, chest, perineum, and thighs should be thoroughly washed with hot water and soap, the hair shaved with a razor, and then all the parts irrigated with a bichloride solution (1 : 1000). The umbilicus should be cleansed, as this is a most important focus for septic infection. The bladder should be emptied by the catheter. New and previously disinfected towels are to be saturated in the bichloride solution or sulphurous acid solution and placed over the parts, thus protecting them during the operation.

All the instruments, ligatures, sutures, and drainage tubes should be placed in a glass tray filled with a solution of carbolic acid (1 : 40), and no instrument should be used without this immersion; if an instrument is to be used a second time during the operation it should be again placed in the tray.

The sponges should be counted, and should consist of the Zymoca flat sponges or "elephant's ears," as they are called in commercial language, and also round sponges and some large ones for use in absorbing blood. Every sponge should be bleached, disinfected, and kept air-tight until wanted for use at the operation.

The antiseptic dressings should be made for the special case, and prepared with the greatest possible care. The number present at the operation should be limited to a few, who have not recently visited the dead-house or a case of infectious disease.

But one assistant should introduce his hand into the cavity beside the surgeon, and this only when it becomes necessary. I have heard recently of a surgeon who requested some medical men present at a laparotomy to introduce their fingers into the cavity to experience the sensation of actually touching the liver in a living person.

The surgeon and the assistant having thoroughly cleansed themselves by washing and by irrigation, are now ready to proceed with the different steps of the operation. The incision should be made in the median line; any deviation from this rule will be found objectionable in many respects. The side incision does not permit the free exploration of the cavity, involves also dividing planes of muscles the hemorrhage from which is troublesome to control, and the primary union difficult to secure. The median incision divides no vessels of any importance, passes through the linea alba, which can be securely sutured, and is not likely to give rise to a ventral hernia. If the incision can be made in greater part above the umbilicus, there is less difficulty in returning the viscera. This incision should be made under warm irrigation; and before the peritoneal cavity is exposed, an exceedingly weak solution of bichloride of mercury should be prepared. The peritoneum can best be divided by using the index and middle fingers as guides, and cutting between them with a probe-pointed bistoury. Some surgeons recommend at this stage paracentesis intestinii to relieve the distended gut. This is attended with danger, because the intestine, being more or less inflamed, will not always contract to close the small aperture.

The surgeon must now introduce his hand, thoroughly cleansed and warmed, into the cavity, and explore. The manipulation necessary depends upon the indication for the operation. It is always well to pass the hand directly to the cæcum and feel if it is collapsed. If it is, there must be obstruction in the canal upon the proximal side and in the small intestine; if dilated, the obstruction is in the large intestine. Volvulus will produce obstruction in stab wound, as has been illustrated. If the operation is for wound, the presence of adherent clots, or fecal extravasation, will often reveal the intestinal wounds in the vicinity. If no wound is found, it may be necessary to withdraw the intestine and to examine it carefully. The intestine should be wrapped in towels or flat sponges, and kept outside of the cavity as short a time as possible. The wounds should be sutured, the cavity sponged dry, and the wound sewed by first placing a continuous suture of catgut in the peritoneal membrane. A second row of sutures of silk or silver should be introduced into the linea alba, and a third line of sutures into the skin. The tube should be introduced between the skin and muscles, and in the lower angle, and the

antiseptic dressings applied with moderate compression.

The after-treatment should consist of opium, to be given in such quantities as seem best to control any pain, to arrest peristalsis, and to quiet patient. The opium should be discontinued as soon as possible, for its use beyond the time to control peritoneal inflammation is attended with detriment on account of the tympanites, and this condition is unfavorable in a wounded gut, for fear of tearing open the wound. The diet should consist of milk and brandy, and great care should be exercised to prevent vomiting, which is an unpleasant complication. In less than a week the patient should be out of danger. and in ten days may sit up, and if complications do not arise, in two weeks he should be well.

The conclusions at which I have arrived from a study of those cases which have occurred to me recently, together with many others during the past few years, and also from those cases reported by other surgeons, are these:

First. That penetrating stab wounds of the abdomen are less fatal than penetrating gunshot wounds, but that the former are fatal in too great numbers to content us with the older methods of treatment.

Second. That if the stab wound has injured the intestine or any abdominal organ, laparotomy is indicated. That it may be indicated also in cases where the gut is not penetrated, but where the gut may become twisted as a result of the stab wound.

Third. That in a penetrating stab wound regarding which doubt exists, the diagnosis should be made certain at once, in order to pursue a proper line of treatment. The indications for laparotomy should be extended also to injuries of any organs within the abdomen.

Fourth. That laparotomy offers no great additional danger to the patient, if properly performed under the strictest antiseptic precautions.

Fifth. That while the number of exploratory laparotomies in stab wounds of the abdomen afford insufficient data upon which to establish any fixed rule of practice, the same principle which is recognized in the performance of laparotomy for gunshot wounds of the abdomen is also applicable to penetrating stab wounds.

Sixth. That the enlargement of the original wound for an examination of the peritoneal cavity will not enable the surgeon to exclude in all cases fecal extravasation, perforation, volvulus, or hemorrhage. These may all exist, and no evidences of their presence be manifest upon inspection through a small opening. My own experience accords with that of Prof Weir, that enlarging the wound may or may not offer the essential knowledge.

Seventh. The size, shape, character, and velocity of the bullet, the attitude of the patient, the kind of weapon used to produce a stab wound, seem to me to influence the question of laparotomy. Any and all of these injuries are likely to produce perforation; and if there is any value in abdominal section, it should be promptly performed, irrespective of the facts connected with the penetrating abdominal wounds.

Eighth. It is possible to have a fatal hemorrhage from the large venous trunks in the abdomen, and this hemorrhage not be discovered until the cavity is about to be closed, when an attempt is made to sponge out the bottom of the peritoneal cavity. This has occurred to me in two cases, in one of which I had closed seven openings, and in the other I had examined the viscera in the cavity. The hemorrhage was checked at the time of the opening, and was not apparent until the close of the operation.

Ninth. That the sutures, if properly applied, will close the perforation in every case, no matter how lacerated these wounds are. The sutures will close the wound in case of resection of the gut, so that no leakage will occur if water is forced through the sutured intestine.

Tenth. The success of laparotomy is to be attained where every arrangement is complete and perfect. Everything depends upon the preparation which is made for this operation, and the antiseptic conditions under which it is performed. The shock, the perforations, the resections of injured parts of the canal, and the after-treatment, are all important steps in this great operation; but the one obstacle yet to be overcome in the management of these cases is the control of the hemorrhage from large venous trunks, and until this object is accomplished, the science of surgery in this operation cannot be said to have arrived at a state of perfection.

In the present unsettled state of opinion, it would seem best not to perform this operation in medico-legal cases without the full sanction and support of a consultation. The courts of law have recently agitated the question of the propriety and the justifiability of this measure in penetrating wounds, and the legal profession have already upon several occasions, to my personal knowledge, found refuge in this operation to defend a criminal on trial for murder.

When laparotomy is placed among the well-recognized operations in surgery, and when all opposition to it has ceased, the credit of this great achievement will be due to the influence of the writings and teaching of the late Prof. Gross. As far back as 1843, he said in his monograph on the "Nature and Treatment of Wounds of the Intestines:"

> "Here the most prompt and decisive measures must be resorted to, or the person will perish from peritoneal inflammation. . . . It will not do for the surgeon to fold his arms and look upon the scene as an idle and uninterested spectator. Far otherwise. He has a duty to perform, and that duty consists in dilating the external wound if it be not already sufficiently large, in hooking up the injured bowel, and in closing the solution with the requisite number of stitches, at the same time that the effused mater is carefully removed with tepid water and a soft sponge."

The remarks of the late Dr. J. Marion Sims gave new impulse to these views enunciated by Dr. Gross nearly half a century ago, and these theoretical opinions were again supplemented by the distinguished work of Dr. Parkes, of Chicago, who made a practical application of the theory in his researches

and experiments upon lower animals. It remained for Dr. Bull to make the practical application of this knowledge available to higher uses, and thus step by step, through nearly half a century, we have arrived at the accomplishment of our object. It is a source of national pride, that laparotomy in penetrating wounds and visceral injuries of the abdomen was conceived, developed, and perfected in America.

A CASE OF RETROPERITONEAL SPINDLE-CELLED SARCOMA WITH EXTENSIVE THROMBOTIC AND HEMORRHAGIC CHANGES.[1]

By WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA

In addition to features of general clinical interest, the following case is worthy of record from the rarity with which spindle-celled sarcomata form large abdominal tumors, and still more so from the remarkable hemorrhagic destruction which the greater portion of the growth had undergone.

Michael D., æt. sixty, machinist, resident of this country for thirty years, was admitted to the University Hospital, September 25, 1885, with a tumor of abdomen. Has been a moderate drinker, has used tobacco to excess. Has been healthy, "never sick a day" until present illness. Family history good; has nine healthy children. About six months ago, he noticed that the abdomen was getting large, but felt no inconvenience, and it was not until two months ago that he began to feel uncomfortable after eating, and began to lose flesh and strength. Has lost about eighteen pounds in weight. His appetite has, at times, been ravenous, and the thirst excessive. Bowels obstinately constipated, no movement without purgatives. No pain of any kind in abdomen, only an unpleasant fulness after eating.

Present condition: Moderate emaciation; weight 117 pounds. Complexion muddy. Temporal arteries prominent and tortuous. Tongue clean; appetite good, but he cannot take large meals on account of sensation of fulness. Says he is in good health, only weak. Passes about seven pints of pale urine of a specific gravity of 1.004, with a trace of albumen; no casts, no sugar. Examination of thoracic organs negative. Abdomen presents a symmetrical prominence in the neighborhood of the umbilicus, rather wide and flat. Superficial veins not distended. On palpation a solid tumor is felt occupying the hypogastric and umbilical regions, and extending laterally into the flanks. It is irregularly nodular on the surface, slightly movable, and the rounded outlines above and laterally can be distinctly felt. Below, the outline is not clear and cannot be defined. Grasped firmly, it can be moved as a solid uniform mass occupying a median position. No one part is softer than another, and there is no sense of fluctuation. Percussion gives a dull note over the tumor, tympanitic above in the epigastric region and in the lateral part of the umbilical. From spleen and liver the mass can be easily separated both by percussion and palpation. There is no pain in handling. Measurement round umbilicus thirty and three-quarters inches. Glands in groin not enlarged, feet not swollen.

He stayed in hospital until November 11th, the condition remaining unchanged, except that he gained three or four pounds in weight, and his general health had improved. The condition of the urine was of interest: for several weeks he continued to pass more than seven pints daily of pale urine of a low specific gravity, with a trace of albumen, but in the last three weeks in hospital the amount fell to about three and a half pints. On October 18th he was made the subject of a clinic, when the diagnosis of Lobstein's retroperitoneal sarcoma was made. The polyuria was attributed to irritation of the renal nerves caused by the pressure of the tumor.

On the 10th of November he went home. Subsequently he was admitted to St. Mary's Hospital, under Dr. O'Hara, and the upper part of the mass, which had become soft, was aspirated by Dr. Mears, and a couple of quarts of bloody fluid removed. He was taken to his home, where he died in April, and I have to thank Dr. Miller, under whose care he was, for an invitation to be present at the autopsy, and for permission to utilize the specimens.

Autopsy, with Drs. Mears and Miller. Considerable emaciation, abdomen distended, discolored in upper part. A solid tumor could be felt occupying a large part of the cavity, firm below and soft above. On exposing the peritoneum a large mass occupied the lower three-fourths of the cavity, pushing up the intestines. The membrane was smooth, in places covered with small grayish-white nodules, and in the flanks there were a few adhesions. At the top of the tumor a coil of jejunum was adherent, and of a dark, pigmented appearance. Many large veins coursed over the surface of the tumor, which was covered by the glistening peritoneal membrane. In the upper, flaccid portion was an orifice, through which blood oozed, and in the peritoneal cavity there were about two pints of fluid of a similar character. The intestines were carefully removed; there was only the one adhesion, already mentioned. The mass, which was covered by peritoneum, occupied a median position, lying upon the spine, and extending to the brim of the pelvis. The hand could be placed behind it and passed down the vertebral column, and into the concavity of the sacrum, and in these regions the tumor had no adhesions. Below and to the left it was loosely united to the lower part of the sigmoid flexure, but the chief attachment was to the brim of the pelvis on either side of the fundus of the bladder, and particularly to the right side. The bladder itself was not disturbed in position; the top of it could be seen lying between the symphysis and the tumor. The adhesions, which were readily separated, were closest to the transversalis fascia on the right side near the pubic bone. The weight was estimated at about eight pounds.

The tumor consisted of two parts, an upper cystic, flaccid portion, and a lower solid one. When opened, the cyst contained rather more than a pint and a half of bloody fluid, with flakes of yellowish-brown material, which also lined the wall, giving an appearance not unlike a large aneurismal sac. The walls were thin, and consisted of a peritoneal investment, within

[1] Read before the Philadelphia Pathological Society, January 14, 1886.

which was a firmer, condensed fibrous tissue. The blood removed at the tapping had evidently come from this sac. A transverse section across the solid part showed a central, firm, dry, yellowish-brown tissue, which cut with resistance, and which was everywhere surrounded by extravasated blood, occupying a position just within the capsule, and in some places extending into the substance. In this section there was nothing suggestive of a neoplasm, the tissue resembled the dry, leathery contents of an old aneurism, except that there was no lamination. Section of the lower part of the mass near the pelvis revealed several soft, grayish-red portions, cerebriform or encephaloid in appearance, and evidently of a sarcomatous nature. They formed, however, a very insignificant part of the entire mass.

There was no special enlargement of the retroperitoneal or mesenteric lymph glands. The stomach and intestines presented nothing abnormal. The pancreas and spleen were unaffected. The liver contained one secondary mass in the left lobe, the size of an orange, and several smaller ones. The kidneys were fibroid, and the ureters and pelves dilated, particularly the right; due, doubtless, to pressure. The heart showed moderate hypertrophy of the left ventricle. Aorta smooth. Lungs much carbonized, and somewhat emphysematous. Brain not examined.

Histological examination: Teased portions showed that both primary and secondary growths were composed of large spindle cells, closely packed together. The remnants of the original growth situated at the lower part of the tumor were quite distinctive, and had not undergone degeneration. There were also, in some places, portions of sarcomatous tissue just within the capsule, separated from the central dry thrombus by freshly extravasated blood. Sections of hardened portions showed a typical spindle-celled growth. The thrombus presented a finely granular basis-substance, between strands of translucent, hyaline material. All traces of cell structure were gone.

Remarks.—The points of interest about this case may be briefly considered under the following heads.

The character of the growth: Spindle-celled sarcomata rarely form large abdominal tumors. In the examination of a considerable number of new growths of all sorts, removed from the peritoneal cavity, I have not met with a similar one.

The situation of origin was unusual. I fully anticipated that we should find it springing from the lumbar retroperitoneum, the common point of origin for large abdominal sarcomata. Here the growth seems to have begun in the subserous connective tissue in front of the symphysis, not from the periosteum, for it was quite loosely attached. It is interesting to note that spindle-celled sarcoma not infrequently originates in the connective tissue of Scarpa's space, a tissue directly continuous with that from which the tumor in question grew.

The looseness of the attachment and the readiness with which the tumor could be lifted out of the abdominal cavity made us regret that we had not yielded to the old man's urgent solicitation to have the abdomen opened.

The character of the regressive changes: So soon as a tumor attains any size we expect to find in it areas of degeneration, fatty, caseous, or calcareous; or, if a rapidly growing neoplasm, hemorrhages. Sarcomata are particularly prone to hemorrhage; indeed, when growing actively, it is rare not to find foci of extravasation in them. The effused blood not unfrequently becomes encysted, and the dark contents appear to result from the liquefaction of the coagulum. In a large tumor several such cysts may exist. Small scattered hemorrhages are more common, and the blood gradually undergoes changes without materially altering the appearance of the growth.

The condition in the case here reported is very unusual, as the greater part of the tumor had become converted into a dry, hard thrombus, while a considerable portion was occupied by a blood cyst, so that the mass resembled a huge hæmatoma rather than a neoplasm. Such general hemorrhagic destruction of a large tumor is not often met with, and I have not been able to find the record of a case with just such extensive thrombotic changes as here described. The mode of production can be readily understood from the appearances presented by the mass. No doubt softening and destruction by hemorrhage first occurred, as existed, indeed, at the upper part of the tumor, which formed a large blood-cyst, the walls lined with thrombi, and in the fluid contents of which were flakes of firm fibrin. This cyst had been much larger, as nearly two quarts of bloody fluid were removed from it by aspiration. Had life been prolonged, the blood thus extravasated would, doubtless, have become inspissated by the absorption of the more fluid parts, and the remainder have been converted into just such a dense, dry mass as existed at the lower part of the tumor. It seems reasonable to infer that the firm, hard thrombus which constituted more than one-half of the entire tumor, was formed in this way. Possibly the hemorrhages beneath the capsule, which were very general, aided the process, though nowhere could a distinct lamination be detected.

The polyuria: Pressure of new growths in the abdomen upon the solar plexus or upon the renal nerves may cause a very great increase in the flow of urine. The irritation in this case was transitory, as the amount fell to normal before he left the hospital. We do not yet know the precise conditions under which this occurs. Instances of it are rare, and we need careful observations on the state of the nerves. Dickinson, in his work on *Diabetes*, mentions a case in which degeneration of the solar plexus was found. Owing to the unfavorable circumstances under which the post-mortem was performed, no dissection of the nerves could be made in this case.

SUPERNUMERARY MAMMARY GLANDS AND NIPPLES.[1]

THREE CASES.

By WILLIAM A. EDWARDS, M.D.,
INSTRUCTOR IN CLINICAL MEDICINE, UNIVERSITY OF PENNSYLVANIA; MEDICAL REGISTRAR, PHILADELPHIA HOSPITAL

That only about one hundred cases (105, Liechtenstern) of polymastia have been recorded will at once

[1] Read before the Philadelphia Pathological Society, January 14, 1886.

appear as the *raison d'être* of this brief communication. A somewhat unusual opportunity for the examination of patients in hospital practice and in the examination of recruits, has convinced the writer that these additional mammæ are not, at least in this country, of very frequent occurrence. It is proper, however, to add that Dr. J. Mitchell Bruce is of the opinion that the number of cases seen by practitioners and not reported must be very great. It becomes somewhat interesting to look into and, if possible, arrive at the cause of these abnormalities. Laycock, in endeavoring to explain the existence of the accessory glands, thinks that the mammæ are simply enlarged and highly developed sebaceous glands, and may make their appearance in any part of the body.

I might cite as a possible example of this theory, Klob's case of an accessory mamma growing on the left shoulder of a man, on the prominence of the deltoid.[1] It was a true mammary gland, and had a nipple about a quarter of an inch in length, the entire gland being about the size of a walnut.

In turning to the morphological significance of these cases, we must consider the character of the mammary glands in the different orders of mammalia, remembering that in the marsupialia and the monotremata the glands possess no nipple, their orifices being mere scattered pores in the skin.[2]

In the Simiadæ, from the anthropoid apes to the marmosets or arctopithecini, "the teats are only two in number," and they are pectoral.[3] In the lower section of the Primates, the Lemuridæ, "sometimes there are one or two pairs of teats on the abdomen in addition to the ordinary pectoral pair."[4]

In the aye-aye (Cheiromys Madagascariensis) "there is but one pair of nipples, situated about one inch and a half in advance of the vulva, and one inch apart."[5]

We are all familiar with the vulvo-pectoral teats of the common carnivora and the inguinal udder of the ruminants. In the Pteropodidæ (fruit bats or flying foxes) and the flying "lemur," Galeopithecus, we find axillary teats.

So if we desire to explain the presence of supernumerary mammary glands in women by the reversion theory, we see that there are numerous places where the accessory organs may grow; yet, as we will see later, the recorded cases seem to differ in their site from all morphological laws.

That our species present the pectoral position of the teats does not show any special superiority, as the glands are found in the same position in the bat, dugong, manatee, elephant, sloth, and the ant-eater.

We do not find the number of teats always in relation to the offspring; as, for example, the rat has twelve, whereas the guinea-pig has but two; again, the tenrec (centetes), an animal somewhat like a hedgehog, has twenty-two nipples, and Owen tells us that in the European hedgehog there are ten, ranging from the pectoral to the inguinal region, adding that the thin, flat mammary gland of this insectivorous animal seems to form a continuous stratum.

Before leaving this part of our subject, it may be interesting to note that Professor Owen[1] describes a female orang-outang with an accessory nipple on the left side, below the normal one and of smaller size.

The case that I am about to record was noted in the spring of 1884, in company with my student, Dr. Thomas D. King, of Springfield, Ohio.

CASE I.—John J. B., æt. thirty-six, a healthy, well-developed man, came under my care for subacute alcoholism, and while examining his chest for impending pneumonia an accessory nipple was noted on the right side almost on a line with and three inches below the normal one, similar in size, presenting an areola with glandular nodules and a few stiff hairs. There was no discharge from either the normal glands or the accessory nipple; it had never caused the patient any inconvenience, beyond a certain hesitancy and delicacy in confessing the abnormality.

In conversation with my patient, I learned that his sister presented the same abnormality, and an interview was arranged.

CASE II.—Mrs. N. M., æt. thirty-eight, mother of four children, the youngest a nursling. The woman was a perfect specimen of the healthy Irish-American female that we so frequently meet.

The accessory breast in this case was on the left side, normal in appearance, somewhat smaller than the other two, but was functionally active with a good flow of milk from a perfectly normal nipple; during my visit the child would nurse indiscriminately from any of the breasts. The woman informed me that she had nursed all of her children in this way. I learned that the supernumerary gland developed coincidently with the others, becoming active as they did and again physiologically barren as their secretion retroceeded.

These two cases, and the two reported by Handyside,[1] open an interesting field in the study of the inheritance of the abnormality. In no case recorded by Bruce (Ibid.) was heredity at all clear. Liechtenstern could find no illustration of heredity among his own cases, but remarks that inheritance was indicated in 7 of the 92 cases recorded in literature.

All the instances of supernumerary nipple that came under observation were situated on the front of the trunk, below the level of the ordinary mamma and somewhat nearer the middle line, but unfortunately for those adherents of the theory of morphological explanation of these cases, abdominal nipples are extremely rare. Bruce, however, describes two cases where one of a pair of nipples was distinctly below the costal cartilages.

Liechtenstern's conclusion, from his own experience and from the recorded cases, is that "accessory nipples and breasts occur in 91 per cent. of the cases at the front of the thorax; and in 94 per cent. of these below the normal." In one of Liechtenstern's

cases, the nipple occurred in the axilla, which is an extremely rare situation. All observers agree in stating that additional mamma or nipples are most frequently seen on the left side. Liechtenstern endeavors to account for this by the well-known fact that the left mamma is, as a rule, more developed than the right, and that mothers use the left more than the right in suckling. He is of the opinion that the same relation exists in the child and virgin.

As to the frequency of this abnormality, I may mention that in Bruce's investigations of 3956 persons 61 cases of supernumerary mamma or nipples were found, being 1.54 per cent. Of these cases 51 were simple cases, presenting a single supernumerary nipple or mamma, 10 were multiple, presenting more than one supernumerary nipple.

A perusal of Mitchell Bruce's exhaustive article would lead one to conclude that supernumerary nipples or mammæ must be much more frequent in England than they are in this country, as, out of 315 persons taken as they come and go in a dispensary service, he found that 287 individuals presented no supernumerary nipples or mammary glands; 24 individuals presented one or more supernumerary nipples or mammæ; and 4 individuals presented appearances which were regarded as doubtful instances of the abnormality. A representation of this result in percentages would be as follows: 91.1 per cent. presented no supernumerary nipple or mamma; 7.619 per cent. presented one or more supernumerary mammæ or nipples: and 1.27 per cent. possessed what was doubtfully regarded as the abnormality. This is certainly a high rate of frequency, even above that of Liechtenstern, who places it at "1 in 500 persons at least." As to the relative frequency of the abnormality in the sexes, it appears from the above statistics, which are undoubtedly the best that are available, that supernumerary nipples occurred very nearly twice as frequently among men as among women; this conclusion also agrees with Prof. Liechtenstern's result. It will be readily understood that definite statistics are extremely hard to formulate in these matters, as some cases will undoubtedly be overlooked unless attention is particularly called to the mammary regions. Again, some of these supernumerary nipples may quite escape detection on account of their want of resemblance to the normal standard; for example, the additional nipple may be wanting in the areola, the follicles, the marginal hairs, or, again, the papilla may be poorly developed, as may also be the terminal depression or opening. We may be misled by a hair springing from the summit of the papilla, as in one of Bruce's cases.

Before leaving the subject, it is, perhaps, well to mention some cases of supernumerary mammæ in unusual situations.

Dr. Fitzgibbon[1] records the case of an individual with double and symmetrical supernumerary nipples below and within the normal, together with two pigmentary deposits, one on either breast higher up.

Accessory mammæ, with nipples, have been found in the axilla,[2] and to Liechtenstern also belongs the credit of describing two cases of dorsal mammæ; his references, quoted by Bruce, are as follows: 1. Ch. F. Paulinus (*Observat. Medico-physic Select*, in the *Miscell. Curios. Academ. Med. Phys. Nat. Curios.*, dec. II. ann. iv. page 203, Appendix); 2. Joh. Otto Helbig (*De rebus variis indicis*, Obs. 194, quoted in *Miscell. Curios.*, etc., dec. II. ann. ix. and x. p. 456, ii.).

Again must we credit Liechtenstern with showing the fallacy in the statement of the existence of inguinal mammæ. He has pointed out the fact that the idea has arisen by careless reference to Roberts's case (see Luschka, *Anatomie des Menschen*, Band I. Abthril. 2) of a woman who had an accessory mamma on the outer aspect of the left thigh, four inches below the trochanter; it was accidentally discovered by the patient's child, who one day attempted to suck the nipple.

Dr. H. L. Turney[1] reports a case of additional mammary gland in the right axilla; it was nippleless, but secreted milk freely from several orifices after each confinement.

Dr. Cohn presented a patient before a meeting of the Berliner Medizinische Gesellschaft, in February, 1885, with an accessory mammary gland in the left axilla, from which milk dribbled away. There was no nipple. Mr. A. H. E. Cameron[2] also records a case of left axillary mammary gland without nipple; and Mr. Bickersteth informs him that he has seen two similar cases of nippleless glandular tumors bearing the characters of mammary glands.

The following case occurred in the practice of Dr. H. R. Wharton, of Philadelphia, to whom I am indebted for the notes:

Case III.—Mrs. S., æt. twenty-seven, in her third confinement, called my attention to a supernumerary nipple on the right breast, situated about three inches below the normal nipple, just at the edge of the mammary gland. It was smaller than the normal nipple, had a well-developed areola, contained milk, and the child could use either indiscriminately. Before her first confinement she thought it was a mole, but at this time it became enlarged and contained milk which escaped freely from it at the time I saw her.

HOSPITAL NOTES.

DISPENSARY FOR NERVOUS DISEASES, BALTIMORE.

Service of John Van Bibber, M.D.

Clinical Notes.

CHOREA.

The increasing frequency of chorea makes the study of this disease most interesting at the present time. In the last two annual reports of the Dispensary for Nervous Diseases I have alluded to the marked increase of this disease, and lately I have been struck by the fact that in two days six cases of St. Vitus's dance applied at this clinic for treatment.

Both in the later text-books and in the journals the theory that heredity plays an important part in the production of chorea has been advanced, but I can discover no reason to think that any one of this series of cases has been brought about by hereditary influence. In fact, while we may find curious instances of a family tendency to choreic attacks, I think the observation is so out of proportion to the number of cases seen, that we must look to some other cause for the marked increase of a disease which, some years ago, was rarely observed. I do not pretend to deny that a neurotic tendency cannot be, and, in most cases, is not transmitted, but I find myself confronted at once with a difficulty in accounting for the development which we are called upon every day to observe at the Dispensary. Heredity can have no influence on the children of parents who have never heard of chorea, and who, from their position in life, have been denied the surroundings which tend to develop the nervous system in its higher and more intellectual side. Hence, in this clinical study of the subject, we must look to some other cause to account for a most interesting and important manifestation of nervous disease.

At the present time what I may term the over-balance of the nervous system in children is remarkable. We see to-day insomnia, headache, and other nervous manifestations among children, which were formerly confined to adult life. Chorea is now, in my experience, almost an epidemic, and it will be the object of these records of the service at the Dispensary to investigate the cause or causes of the increase of St. Vitus's dance, to determine by experience the best method of treating the disease, and to endeavor to suggest the means to prevent this unusual and alarming tendency. For this purpose accurate notes will be taken of all cases presented for treatment, and in a subsequent record the details of another series of cases will be submitted.

I select from the notes of my assistant, Dr. H. C. Ohle, the following data of six cases of chorea which applied to the Dispensary for treatment respectively on January 18 and 19, 1886.

Case I.—J. C., a girl nineteen years of age, is a seamstress by occupation. On inquiry, we learn that this is the third attack from which she suffers, they having occurred at intervals of about one year. Some time before symptoms became pronounced she lost her appetite, became nervous, slept badly at night, and was much depressed; her menstrual function, which, previous to this time, had been normal, became irregular. There was a like history in the two former attacks.

On arising about two weeks ago, after having spent a restless and nearly sleepless night, she felt very much depressed, and had a hysterical crying fit; from this time on, she was unable to attend to her work. She would let articles drop from her hand, seemingly unable to prevent it, and noticed curious twitchings and movements of her head, which extended to her arms and legs. I further learn that she works all day in a close room, and has been in the habit of going out very often in the evening to dance, etc., which, no doubt, tended to debilitate her.

On examination, we find that the head and the arms and legs of both sides are involved in the choreic movements, which seem to be aggravated somewhat after entering the room, possibly owing to the excitement induced by the examination. Patient is very anæmic, though apparently stout; has no appetite, cannot sleep at night, and is extremely depressed and hysterical. She was directed to remain as quiet as possible, to avoid all excitement, to remain in bed late in the morning and to retire early at night; and, as the weather was inclement, forbidden to go out. The therapeutical treatment consisted principally in conium, bitter tonics, and iron. Quiet, rest, and suitable food were insisted on, and these I have every reason to believe were carried out. She was discharged well on Feb. 18th.

Case II.—M. G., a girl sixteen years of age, lives at home with her parents. This patient had her first attack when twelve years of age, at which time her menstrual function was established; she has suffered recurrent attacks every spring since then, this being the fourth, which began one week ago. Patient is very tall and slender, extremely delicate in appearance, poorly nourished, and anæmic. She is subject to menorrhagia.

On examination, we find that the muscles of the *right* side of the head and arm are alone involved in the choreic movements, which are severe in character. She gives the usual history of anorexia, interference with sleep, etc. She is much depressed, and has a morbid fear that her trouble may prove fatal. She was directed to remain in bed late in the morning and to retire early at night, to rest, and to keep as quiet as possible, avoiding all excitement; was ordered conium, iron, and bitter tonics, and later on, arsenic. She grew worse after the first week of treatment, which was accounted for by the fact that she attended several meetings of the Salvation Army, in which she seemed to take especial interest. These were promptly prohibited, and the necessity for quiet and rest and avoidance of all excitement made clear to her; from the time she observed these directions she has much improved. Appetite is good and the choreic twitchings are reduced to a minimum. She is still under observation, although medicines have been discontinued, with the exception of iron.

CASE III.—A. H., a girl thirteen years of age, living with friends. Symptoms were first noticed about two months ago, shortly after the death of both parents, to which fact her friends attribute the chorea, the patient having been well and hearty previous to this time. After this sorrow she commenced to grow pale and thin, ate little food, and became excitable. The choreic movements were noticed at this time, but were thought to be the result of shock from the loss of her parents. They grew worse, however, and after two months she applied for treatment.

On examination, we find that the whole body participates in the choreic twitchings to a most excessive degree. She is unable to remain quiet, the movements persisting during the night, so that it is impossible for her to obtain sleep. She is very anæmic, and has no desire for food. She was directed to keep quiet, to rest in bed as much as possible during the day, and at night to take a hot sponge bath to spine, to be followed by rubbing with a coarse towel; potassium bromide was given to induce sleep. In addition, iron, bitter tonics, and conium were ordered. Isolation from other children was insisted on, so as to insure more perfect quiet and rest. She improved rapidly under this treatment, and after a week the potassium bromide was withdrawn, as sleep was obtained without it. Her appetite has become established, and she has so far improved that it was thought unnecessary for her to remain in bed during the day. She is still, however, under observation.

CASE IV.—J. B., a girl twelve years old, was presented for treatment by her mother, with the following statement: one year before, she had an attack of chorea, which was very protracted; she attends school, and is a very close student. After recovery from her first attack, she enjoyed good health until about six weeks ago, when she lost her father, to whom she was much attached. After this time she began to fail perceptibly, developing choreic movements.

On examination, we find that movements are confined to the left side of face and left arm; there are slight twitchings in left leg. She was very excitable, crying readily when questioned, which aggravated the twitchings greatly. She seems to be well nourished, possibly a little pale and anæmic. She sleeps little at night, which her mother thinks is owing more to her mental excitability than to the choreic twitchings; appetite is poor. Notwithstanding her condition, she insists on going to school.

Her mother was advised to take her from school, to keep her quiet in bed as much as possible, and away from other children. She was given conium, iron, bitter tonics, and later on, arsenic; at night potassium bromide was given. She improved slowly, and not so rapidly as the cases before cited, which can be accounted for by the fact that she was hard to manage, being very wilful and not ready to carry out the treatment. If she could have been treated under more favorable circumstances in a hospital, where the plan of rest and quiet could have been carried out, she would undoubtedly have progressed as favorably as the other cases.

CASE V.—M. G., a girl ten years of age, was presented for treatment, with a history of having been frightened two weeks ago, since which time she has had choreic movements in her arms. On inquiry, we learn that she had a previous attack when about six years old, which was, however, mild in degree. On examination, we find that the muscles of face and those of arms are involved to a great extent. Patient is very poorly nourished, and apparently badly cared for. Her mother was directed to keep her quiet, to give her at night a hot spinal sponge bath, followed by rubbing with a coarse towel, and, above all, to see that she got appropriate food, which directions were promised to be carried out. In addition she was given conium, elixir ferri et calcis, and calcic phosphate.

The girl is now much improved, the choreic movements have almost disappeared, although she is still delicate and pale; she is still under observation, the administration of elixir being continued.

CASE VI.—F. H., a boy nine years old, presented for treatment by his mother, with history of having enjoyed good health up to within two months. He attended school and was very studious up to that time, when he began to lose interest in his studies; about four weeks ago, he developed chorea on right side, which is excessive in degree. On examination, we see that the boy is delicate and puny-looking, and that the choreic movements are confined to the right side of the face and right arm and leg, and are violent in character, nearly twisting him around as he stands. He is unable to sleep, and complains of vague pains on affected side; appetite is very poor. Quiet and rest in bed as much as possible were directed, and isolation from other children to avoid excitement. In addition, the hot sponge bath and rubbing with coarse towel daily. Conium, iron, and bitter tonics, and later arsenic, at night potassium bromide, were given for a time. In this case, also, the progress was not as rapid or as favorable as desired, but it was impossible to carry out the plan of treatment ordered, as the mother is a widow and has eight other children.

In each of these cases a functional heart murmur was found.

Remarks. Of these six cases, three had suffered from former attacks of this disease, one having had three attacks, one four, and one was suffering from St. Vitus's dance for the second time. The three remaining cases were caused by fright or grief, and all were unconnected with rheumatism. I consider it to be rather remarkable to have six cases of chorea apply at a small clinic in two days, and I shall take special care to have accurate notes of this class of patients taken in the future, looking to the value of statistics for a specified time.

In an article on the "Rational Treatment of Chorea" (*American Journal of Neurology and Psychiatry*, May, 1884) I formulated the treatment which was successfully carried out in eighty-six cases of this disease, and since that time I have had no reason to vary this method materially. This consisted of a combination of medical regimen and proper physical care, and is briefly detailed in the cases above reported. Rest, tonics, food, and proper hygiene, are the principal factors in this treatment, and in most cases rest is by far the most important element. After confinement in bed during the day I find it necessary to refresh the system, and this can be done by the hot spinal douche and subsequent frictions.

In the next series of cases I will, as far as possible, give my ideas concerning the cause of chorea and the best method of preventing its development.

MEDICAL PROGRESS.

Calomel as a Diuretic.—Led on by the accidental observation that, in a case of dropsy, small repeated doses of calomel induced diuresis of high grade, Jendrássik exhibited the same drug in seven cases of heart disease in which diminished urinary secretion and static œdema were present. The maximum amount of urine passed daily under this treatment varied from four to eighteen pints, and averaged over nine pints. The maximum once attained, the amount passed gradually declined. Three grains of powdered calomel, three to five times daily, was the quantity usually given. It was found that large doses were inefficient, as they produced diarrhœa, while in the smaller doses, subjective metallic taste and other symptoms gave evidence of the absorption of the drug. It is interesting to note that a period of at least one and sometimes two or more days elapsed between the commencement of the treatment and the occurrence of diuresis.—*Centralb. f. d. ges. Therap.*, February, 1886.

"Opuscula Practica."—In Part VI. of *The Asclepiad* Dr. Richardson refers to a remedial agent which he believes will play as useful a part in surgery as the ethylates and "colloids" originally introduced by him. This is oxalic ether ($C_6H_{10}O_4$), a colorless liquid, sp. gr. 1.090, boiling at 183° C., having a pleasant odor, but a decidedly biting taste. It dissolves readily in alcohol and in ethylic ether; it is also soluble in water to the extent of four per cent., but after a time water decomposes it, alcohol and oxalic acid being formed. Potash and soda solutions convert it into alcohol and oxalates of the bases, whilst ammonia solutions convert into alcohol and oxamide. When administered hypodermically, oxalic ether is decomposed at the point where it is introduced, and acts there perhaps exclusively, the action being to coagulate the albuminoid structures, and to produce almost painlessly a free and dry eschar, without marked constitutional disturbance, unless used in excess. Dr. Richardson looks upon oxalic ether as a destroyer of tissue rather than a caustic, and believes it will prove of service in application either by the brush or by needle injection for the removal of morbid vascular growths. It is prepared by the action of oxalic acid upon absolute alcohol.

A solution of one drachm each of camphor and spermaceti in two fluidounces of rhigolene is recommended as useful when applied on cotton-wool to burns. The evaporation of the liquid is said to induce instant relief from pain, and there is left a thin film of camphor and spermaceti covering the injured surface. Dr. Richardson also calls attention to the much overlooked value of sponge as a poultice carrier, especially for mustard. After the mustard paste has been made of a smooth and even consistency, it should be taken up on a clean sponge, the sponge laid in the centre of a soft white cloth, the corners of which are tied, and the smooth convex side of the sponge is then applied to the surface of the skin. The mustard sponge, warmed again by the fire and slightly moistened, can be applied two or three times, and remains useful for several hours. The sponge can afterward be easily cleaned in warm water.

Hydrotherapy in Cerebral Rheumatism.—The following conclusions are embodied in a recent thesis by Dr. H. Dupré:

Hydrotherapy should be employed in cases of cerebral rheumatism with hyperpyrexia and delirium, with or without suppression of articular inflammation.

The state of the pulse, the temperature, and the nervous phenomena are the symptoms upon the presence of which treatment is instituted, and hesitation is not permissible in view of the danger to which the patient is exposed.

General baths are to be preferred to other methods of treatment. In acute cases the temperature of the bath may range between 88° and 68° F., usually beginning at the high temperature, which is slowly diminished by the addition of cold water to the bath.

No absolute contraindications of this method exist, but the possibility of resultant congestions, pneumonia, pleurisy, and syncope should be borne in mind.—*Revue de Thérapeutique*, January 15, 1886.

Maury's Ointment.—Under this name, an unctuous solid was first formulated and introduced into the Philadelphia Hospital, some eight years ago, by Dr. Maury, then a visiting physician of that institution, for the external healing treatment of sores, ulcers, etc., in general, and as especially serviceable in external affections of the skin dependent upon venereal origin. Since that time, in the medical practice of the hospital referred to, it has been constantly employed by the resident physicians, with a more than ordinarily uniform success.

The original formula contained simple cerate (Ceratum, U. S. P.) as the diluent, and not cosmoline, as hereafter mentioned:

R.—Nitrate of mercury ointment	. .	℥j.
Powdered rhubarb,		
Powdered opium	. . .	āā ʒss.
Cosmoline	. . .	q. s. ad ℥j.

Triturate the rhubarb and opium together with the cosmoline, until a perfectly smooth, homogeneous product is obtained. Then admix with it the citrine ointment, after having previously rubbed the same with about one fluidrachm of glycerin to remove any granulation present, using in the latter process a bone spatula.

The ointment, when freshly made with cosmoline as the diluent, is a soft, unctuous, greenish-brown solid, readily melting at the temperature of the body, and capable of being absorbed by the skin. It changes rapidly, on exposure to air, to a very deep brown color. The partial change of chemical nature, as evidenced by the change of color, does not appear to affect the medical qualities of the article in question, as every-day usage has fully demonstrated that the old ointment is as efficacious as the new.

Its mode of application is somewhat peculiar and worthy of especial mention. The part to which the ointment is to be applied must first be poulticed with a hot "Labarraque poultice," that is, a poultice of flaxseed meal, made with hot Labarraque's solution, instead of the hot water ordinarily used. After remaining on for awhile, the poultice is removed, and frequently takes with it portions of dead tissue. The skin is then carefully dried, the ointment spread upon soft lint and applied twice a day, or varying according to the severity of the case until the sore, is healed.—*Am. Journ. of Pharmacy*, Feb. 1886.

Chronic Chloroform Intoxication. — During thirty two days, Paul Bert daily induced chloroform intoxication of thirty minutes' duration in a fifteen pound dog. The narcosis was effected by the administration of 150 grains of chloroform in 24 gallons of air, and usually occurred in from ten to twelve minutes. At first the animal struggled actively against the inhalation, and exhibited a violent stage of excitement; but, as time went on, this stage gradually disappeared, as did also the resistance. On the twenty-sixth day the chloroform was withheld, and at the usual time of the experiments the dog began to whine "like an ætheromaniac deprived of his narcotic," and this condition continued during the entire night. From the third day of the experiment the dog ate but little, and from the twelfth day on he was markedly somnolent, but responded when called, and drank much. During the thirty-two days he lost fourteen per cent. in weight, and during the latter part of this period developed conjunctivitis and perforation of the cornea. Neither albumen, sugar, nor chloroform were at any time present in the urine. The animal died on the thirty-second day during narcotization, and an examination revealed fatty degeneration, most marked in the liver, heart, and kidneys.—*Centralb. f. klin. Med.*, January 2, 1886.

Preventive Inoculation of Yellow Fever.—According to the *Siglo Medico* of December 13, Dr. Meyrignac, of Panama, is inoculating for yellow fever, which is very prevalent among the workmen and employés of the Canal Company. Like Dr. Carmona, he employs the sediment of the urine of yellow fever patients, which contains the zoöspores of the peronospora lutea, and injects it, dissolved in distilled water, with a Pravaz's syringe. Three hundred Mexicans were inoculated before the epidemic of 1884, and not one has died. Inoculation is generally followed by an abortive attack of yellow fever, the symptoms being benign, slight, incomplete, and of short duration. This modified yellow fever seems to confer complete immunity from a second attack. The Government of Mexico has recommended the practice, despite the opposition of its medical advisers.—*London Medical Record*, January 15, 1886.

The Phosphorus Treatment of Rickets.—The following is a report by Dr. Boas on the treatment of rickets with phosphorus. Twenty cases of rickets of different degrees were treated in this way. Of these twenty children, twelve had the breast temporarily, only four somewhat longer than half a year, and eight were brought up by hand. As substitutes for the mother's milk, various kinds of infants' food were used —in one case Swiss milk. In six cases, the conditions of the dwellings were most unfavorable. The phosphorus was prescribed in daily doses of one to two teaspoonfuls of an emulsion of one centigramme (one-fifth of a grain) of phosphorus to 100 grammes (3½ ounces), during a period of from one to three months. At the same time, an appropriate diet was given. The effects of this treatment on the ossification and general functions were highly satisfactory. Twelve patients after three months' treatment were able to stand and to walk with comparative safety; in others the effects were less speedy, but an increasing firmness of the bones was evident. Dentition passed very favorably, without undue disturbances, notwithstanding the rapid succession of teeth. In one case of spasm of the glottis, improvement took place eight days after the commencement of the treatment. The general health of the patients was in every instance benefited. In two cases, injurious effects were observed in consequence of overdosing; instead of one to two teaspoonfuls of the emulsion, a dessertspoonful daily having been given by mistake. In one case after eight days' continued use of such large doses, want of appetite, pain, fever, and swelling of the inframaxillary region, with the characteristic signs of diffuse phlegmon, set in. The abscess was opened, after a fortnight's fomentations, by incision, and a teaspoonful of pus mixed with blood was discharged. The incipient phosphorus-periostitis was arrested, and the patient soon recovered. In the second case, a child (three years of age) had already taken five bottles of the emulsion, equal to five centigrammes (five-sixths of a grain) of phosphorus apparently without injury and with evident improvement of the general condition. Then, as in the first case, phosphorus-periostitis manifested itself; and, on opening the abscess, rough necrosed bone, denuded of its periosteum, was discovered by the probe. At the same time, the child complained of violent pain in the epiphyses of the hands, thighs, and legs; this patient also made a favorable recovery. In both of these cases, phosphorus mixed with saliva had entered into the open alveoli. In conclusion, Dr. Boas points out the beneficial influence of even minute increasing doses of phosphorus on the nutrition of the bones; but at the same time he enjoins great caution, lest overdosing may take place.—*The Practitioner*, February, 1886.

Amyl Nitrite as a Physiological Antidote in Cocaine Poisoning.—Schilling records a case of severe cocaine poisoning, in which, after the intragingival injection of two drops of a twenty per cent. solution of this drug, motion and sensation entirely disappeared. Complete amaurosis and deafness were present. The patient could swallow well, and called to her husband, who was absent, complaining of cold and darkness. Schilling, recognizing the condition as one due to contraction of the cerebral vessels, exhibited nitrite of amyl. The face of the patient immediately became suffused, and she cried, "Now it is light again." After three inhalations she was in condition to reply correctly to all questions, and soon after returned to her home.—*Centralb. f. d. gesammte Therap.*, Feb. 1886.

The Action of the Alkaline Metals and of the Alkaline Earths.—Curci finds that, in cold-blooded animals, potassium paralyzes first the nervous and muscular systems, and finally the heart. In mammals the heart is first affected.

Sodium first increases nervous and muscular excitability, producing convulsions, and tetanus of the respiratory muscles. Later appears paralysis, first of the brain, then of the cord, and finally of the heart.

Lithium induces the same phenomena as does sodium.

Calcium causes an anæsthesia, progressing centrally from the extremities, with cardiac paralysis when exhibited in very large doses.

Magnesium exerts effects very similar to those produced by calcium, except that the heart is affected much earlier.—*Centralb. f. klin. Med.*, Jan. 2, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, MARCH 6, 1886.

LAPAROTOMY IN WOUNDS INVOLVING THE INTESTINES.

IN the present number of THE MEDICAL NEWS we give the concluding portion of an interesting paper by PROF. DENNIS on "Laparotomy," the chief object of which is to recommend this operation in cases in which it is reasonable to suspect that a wound or injury of the wall of the abdomen is accompanied by perforation or rupture of the bowel. As we understand the author, he would have the abdomen opened for the purpose of diagnosis and of treatment much more frequently than has yet been common. It is well known that the extent of an injury inside of the cavity of the abdomen can at best be only suspected from the symptoms which follow it, and it would appear reasonable—now that exploratory openings in the abdomen can be made with such comparative safety—to give a patient with either a gunshot or stab wound of the abdomen what may be his only chance of recovery, by cutting down and learning the exact nature of the injury so as to apply the proper surgical remedy.

Prof. Dennis first discusses the applicability of laparotomy to stab wounds of the abdomen and argues for its frequent employment. In studying his argument it does not escape our attention that his own statistics do not furnish the fullest support to his views. However, we agree with his conclusions in regard to the treatment of these wounds. It is now a year since we expressed the opinion that stab wounds of the abdomen may often be regarded as properly subject to laparotomy. At that time we cited the successful case of Tiling, published in 1884, in which a stab wound of the stomach was treated by suturing, after laparotomy. This result is very encouraging. But the same can hardly be said of other reported cases in which the belly was opened, no visceral injury was found, and death followed. These suggest that we must not let our zeal outrun our discretion. Let the belly be opened without timidity, indeed, but also without temerity. Countless stab wounds of the abdomen have been followed by recovery, and many more may yet end as happily; so that the case is not to be thought so desperate as to warrant subjecting a patient to the real risks of laparotomy, except when there is more evidence that the bowel has been punctured than coldness, localized pain, and feeble and rapid pulse.

The case is somewhat different in regard to gunshot (or pistolshot) wounds, for these are so usually fatal that the faintest suspicion of injury of the intestine would seem to justify laparotomy. The opinion of Otis, that gunshot wounds of the small intestine are invariably fatal if left to themselves, has never been discredited, even in the case reported by Dr. Andrews, of Chicago, in which a pistolball, shot into the abdomen above the navel, was passed from the anus a week later; for there is nothing to show that it went into the small intestine. The rule is that gunshot wounds involving the bowel will cause death unless surgical interference averts the catastrophe, and any other result is as rare as it is fortunate. It is further highly probable that any gunshot wound of the abdomen will involve the bowel, and these facts constitute a warrant for surgical interference which is strongly supported by the successful operations already reported, and which is not at all impaired by the operations which have failed to save the patient's life.

In regard to opening the belly after the infliction of violent blows upon it, or after the passage over it of the wheels of vehicles, followed by symptoms of laceration or bursting of the bowel, we think the greatest caution should be exercised, and the cases cited by Prof. Dennis lead us to this conviction. On the whole, we think no more can be said than that it may be regarded as justifiable to operate in a case in which there is not a very strong probability that the injury would prove fatal without respect to any rupture of the intestine.

In conclusion, we would reassert the opinion expressed a year ago in these columns, in regard to the entire class of injuries of the abdomen in which the bowel may have been pierced or ruptured: that active interference may, and should, be instituted much oftener than it is. We cordially commend the conclusions of Prof. Dennis, with the arguments on which they rest, to the thoughtful consideration of our readers.

FOOD INSPECTION.

THE supervision of the food supplies of the people is one of the most important obligations of a munici-

pality. While the price and the quality in a measure must be left to the ordinary operations of trade, the law should intervene to prevent adulterations, and the manufacture and sale of any articles intended for human consumption that are injurious to health. In order to carry out this object the law should define what is meant by adulteration in its various forms, and designate what is unwholesome food, and advise the course of procedure in condemning, withdrawing from the market, and disposing of any "diseased, or unsound, or unwholesome food, or food unfit for the use of man."

The organization necessary for administering such regulations, as well as many other measures connected with the preservation of the public health, already exists in many States in the form of a State Board of Health. Already in several instances the powers of State Boards have been enlarged so as to include the supervision of food supplies. By vesting authority in a central board it is not intended to relieve local boards of the responsibility of supervising food of a perishable character, such as meat, fish, game, vegetables, etc., which require daily inspection; but on the contrary to lend a moral support, and furnish a means of coöperation in effecting a common purpose.

While the main object of legislation against adulteration is the protection of the public health, it yields a further advantage by its economic results. This fact is prominently set forth in connection with the administration of the Massachusetts food-inspection law. Of the articles liable to adulteration, such as milk, butter, spices, vinegar, cream of tartar, and some drugs, consumed in 1884, of the value of $15,000,000, five per cent., or $750,000, were saved to consumers through the enforcement of the act.

In most European countries, laws both general and municipal have long been in existence, which regulate the manufacture or sale of articles of food. In this country most States have statutes relating to special articles of food. Some of them have a purely commercial object; others are intended for the protection of the public health. Beyond enacting a law prohibiting the importation of damaged and adulterated tea, which has been productive of good results, the National Government has done little to insure the purity of food. The bill of Senator Edmunds recently introduced in the United States Senate is intended to supply this deficiency. The passage of the bill and the strict enforcement of the law thus enacted will go far toward securing the purity of staple articles of food, and in establishing the reputation of our products in foreign markets, and as a consequence will be very beneficial to our export trade.

Among the States in which the importance of food inspection has been recognized may be mentioned Massachusetts, New York, and New Jersey. They have recently adopted carefully prepared laws for the prevention of the adulteration of food and drugs. These laws have been engrafted upon those of the State Board of Health. One of their objects is the protection of trade by preventing adulterations; but the vital purpose is to take cognizance of adulterations which are injurious to health, and to prevent the sale of deleterious articles of food.

For the execution of the law the appointment of inspectors and analysts is necessary. Test offices should also be established and provided with the necessary apparatus for the chemical and microscopical examination of all articles submitted by the inspectors, and also by the public, as everyone should have the privilege of ascertaining the composition of any suspected article of food.

Adulteration has been applied to a great variety of foods, beverages, and drugs, but the practice is common in only a comparatively small number of articles, and to these special attention should be directed. Chief among these are milk, butter, cheese, spices, vinegar, sugar, ground coffee, tea, oils for consumption, cream of tartar, spirits, and various sorts of drugs. Meats, fish, and vegetables, and other perishable articles, will require constant supervision. The examination of the flesh of animals should be specially critical. Provision should be made for examining all cattle immediately before killing, and for inspecting the meat before it is exposed for sale in the markets. If all slaughter-houses were placed under sanitary control, and the business of slaughtering concentrated in abattoirs, this work would be rendered practicable and efficient.

It is the practice in London to condemn the flesh of animals infected with certain parasites, as the *trichina* in pork, the *cysticerci* in pork and beef, and *flukes*, which infest the livers of animals; that of animals suffering from fever or acute inflammatory diseases, as rinderpest, pleuro-pneumonia, and the fever of parturition; that of animals wasted by lingering sickness, such as phthisis; that of animals which have died from accident or from natural causes; and also all meat that is tainted or that is sufficiently decomposed to be discolored or to have a putrid smell. The flesh of animals that have been exhausted, excited, or tortured before death has frequently been found to be unwholesome.

Under certain conditions sausages are a most dangerous food on account of a virulent poison which is produced by a sort of modified putrefaction. Poisonous effects are generally observed in connection with sausages which are mouldy and soft in the interior, and which emit a strong-smelling odor. Other kinds of animal food when in a decayed or mouldy condition may occasionally produce similar

effects. Fish, poultry, and game must be examined for signs of decomposition.

Fruit and vegetables must be objected to mainly on account of advanced decomposition. Mouldy food of all kinds is dangerous and should be condemned. The testing of canned goods for poisonous substances, and the examination of various articles of food requiring analysis must be performed in the laboratory, the duty of the inspector being confined to procuring samples of suspicious articles for investigation.

A uniform law in all the States, covering the subjects above suggested, would have a powerful effect in ridding the market of spurious and unwholesome articles of food. The purposes of the law could be secured by notification and warning, and by prosecutions and penalties, and in some cases by confiscation of the condemned articles.

DREAMS.

In a recent article upon dreams, we referred to the views that Wundt holds upon the subject. A consideration of sleep in regard to its etiology precedes that of dreaming. Wundt regards it as certain that sleep belongs to periodical biologic processes, and consequently its most intimate source or origin is to be sought in the central nervous system. As to where the hypothetical centre of sleep is located, we do not know; nevertheless, according to the normal conditions of sleep we must admit that this centre is none other than the organ of aperception itself. Aperception, of course, will not be confounded with perception by the reader. Perception is the simple cognizance of a sense impression—it is a message received at the central office; but in aperception consciousness or reflection is exercised—the message is not only received, but read and understood. The phenomena which appear as a consequence of sleep prove that from the aperception centre the effects emanate which involve the entire central nervous system, presenting the distinct character of effects of arrest. They are manifested by the depression of cardiac and respiratory movements, by lessening of all the secretions, and diminution of reflex excitability; the psychophysical side of these central arrests consists in this, that exterior irritants of moderate energy cannot be perceived, especially cannot be subjected to aperception, and that probably in their turn the reproductions also gradually disappear.

The profoundness of sleep can in some degree be judged by the energy of the irritant necessary to awaken the sleeper. It is proved by experiment that sleep is most profound shortly after it begins; and that it then is replaced by drowsiness. At first, sleep is probably in most cases a state of complete absence of consciousness, such as occurs in syncope, which appears to be only sleep occurring in abnormal circumstances. The arrest of central functions which causes the beginning of sleep, determines besides a series of secondary alterations, which may also be considered the effects as well as the partial phenomena of sleep. Very probably these alterations have as their intimate origin the arrest of the innervation of the vasomotors, and of that of respiration, because all the consecutive phenomena are notably increased by disturbance of respiration. It is probable, too, that arrest of the two nervous centres produces disturbance in the circulation, and also a similar condition in the alternative exchange of materials in the brain.

While new researches are necessary for the determination of some of these points, we can conceive that there will be developed by the conditions that have been mentioned states of irritation which during sleep triumph over the existing arrests, thus suppressing the state of complete absence of consciousness in order to produce in its place a consciousness modified by the particular conditions in the midst of which it is manifested. This modified consciousness is the condition of dreaming. "Since in dreaming representations are reproduced and sensorial impressions are made objects of perception and subjects of aperception, the functions of consciousness appear reëstablished in the dream." The consciousness is modified in two respects: first, the reproduced representations have the character of hallucinations; and, second, the aperception is so changed that the appreciation of facts of memory shows essential alterations.

Wundt regards most of dream representations as really illusions, since they emanate from sensorial impressions which, though weak, continue during sleep. An inconvenient position taken by the sleeper causes the representation of painful work, perilous ascent of a mountain, etc. A slight intercostal pain becomes the point of an enemy's dagger, or the bite of an enraged dog. Difficulty in respiration is fearful agony caused by nightmare, the nightmare seeming to be a weight rolled upon the chest, or a horrible monster which threatens to stifle the sleeper. An involuntary extension of the foot is a fall from the dizzy height of a tower. Flying is suggested by the rhythmic movements of respiration. Further, "those subjective visual and auditory sensations which are represented in the waking state as a luminous chaos of an obscure visual field, by humming and roaring in the ears, and especially subjective retinal sensations, have an essential *rôle*," according to Wundt. "There are shown to us innumerable birds, butterflies, fish, multicolored pearls, flowers, etc." But if there be some cutaneous irritation, these visions are usually changed into caterpillars or beetles crawling over the skin of the sleeper.

The sleeper sometimes dreams of his appearing on the street, or in society, only half dressed; the

innocent cause is found in some of the bedclothes having fallen off. Wundt quotes from Scherer the statement that those dreams characterized by the presence of water, usually result from the sleeper's bladder being full, and the pressing need of urinating. "Sometimes he sees wells open before him; sometimes he is upon a bridge, and is looking down upon the water, or, perhaps, in virtue of an entirely natural association, sees floating in every direction a vast number of pigs' bladders." An inconvenient position of the sleeper, a slight hindrance to respiration, or interference with the action of the heart, may be the cause of dreams where one seeks an object without being able to find it, or has forgotten something in starting upon a journey. The movements of respiration may suggest to the sleeper, as previously mentioned, flying, but this flight may be objective, and instead of himself flying, he sees an angel descending from the heavens, or a luminous chaos where birds are swiftly moving.

The representations of dreams having sensorial origin may have mingled with them those which arise solely from the reproduction of past memories. Thus parents or friends cut off in the flower of life, ordinarily appear in dreams because of the profound impression which their death or burial has made; "hence the general belief that the dead continue during the night their intercourse with the living."

THE FORMATION OF A NATIONAL SOCIETY FOR CLINICAL MEDICINE.

In view of the unquestionable advantages which have followed the organization of special societies in the different departments of medicine, we are informed that it has been determined to organize a society devoted to the interests of clinical medicine and pathology. Preliminary meetings have been held in New York during the winter, at which the project was thoroughly discussed, and favorably considered. A preliminary organization was effected on December 29, 1885, and a committee, consisting of Drs. Francis Minot, of Boston, Wm. H. Draper, of New York, William Pepper, of Philadelphia, R. Palmer Howard, of Montreal, Alfred L. Loomis, of New York, William H. Welch, of Baltimore, Francis Delafield, of New York, and James Tyson, of Philadelphia, were appointed to notify those who were chosen for original members of their election, and to make the necessary arrangements for the first meeting, which is to be held in Washington on June 16th and 17th.

By the formation of this Association, each of the natural divisions or specialties of medicine will now be represented in this country by a special society. This new organization enters upon a wide field of usefulness and begins its career under the most promising auspices.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 15, 1886.

The President, C. A. Leale, M.D., in the Chair.

Dr. Frederic S. Dennis read a paper on

LAPAROTOMY IN THE TREATMENT OF PENETRATING WOUNDS AND VISCERAL INJURIES OF THE ABDOMEN.

(See pages 225 and 253.)

Dr. Joseph D. Bryant said that he had listened with much interest and great individual benefit, to the paper of Dr. Dennis. On account of the expression of his views on previous occasions, it was hardly necessary to say that he was in favor of laparotomy; but it was pertinent to ask, What is laparotomy in the sense in which it presents itself to the profession? There are two distinct forms of the operation: First, exploratory laparotomy; and, second, laparotomy in its entirety. Having given the definitions of these two operations, Dr. Bryant remarked that it is a common custom to characterize as laparotomy the simple exploratory incision.

This operation, he said, he would employ far more frequently than is at present the case; believing, as he does, that when performed under proper conditions it exposes the patient to no unusual danger. In illustration, he referred to Lawson Tait's wonderful success in opening the peritoneal cavity. Exploratory laparotomy is a justifiable operation. It is perfectly simple and easy to open the abdomen; but when it comes to making a thorough examination of the various viscera, arresting hemorrhage at all bleeding points, suturing the intestines, and performing the toilet of the peritoneal cavity, it is a very different matter. This is a procedure which requires a long time—from one hour to two or three. Dr. Bryant said that he called attention to this point in order that the gravity of the operation of laparotomy in its entirety might be fully understood. It is certainly one, therefore, which is attended with a very considerable amount of danger.

Whether shock is present or not, it is justifiable to perform exploratory laparotomy. Whether the exploratory incision is to be made in the median line or not, depends on the direction of the violence producing the wound. If this is toward the median line, the incision may be made in the latter; but if the direction is from the median line, the incision is to be made at the seat of the external wound.

As to the rate of mortality when there is a protrusion of a viscus through the abdominal wound, he has found that statistics show that from 25 to 30 per cent. of all cases recover when the intestine, or other part, has been sutured and returned to the abdominal cavity, and the external wound closed. In penetrating gunshot wounds of the abdomen, treated on the expectant plan, the statistics of the Crimean war show that 7½ per cent. of the cases recovered.

It was remarkable, Dr. Bryant continued, how gradually laparotomy had been led up to, from the days of Fallopius, in the seventeenth century. He then said that he would not consider as a case of laparotomy in its

entirety, one in which there were found no injuries of the intestines or other viscera. If this were the case, it was merely an exploratory laparotomy.

Speaking of symptoms, he said in regard to shock, that it is a principle pretty well established that penetrating gunshot wounds of the abdomen, provided they do not cause hemorrhage or the injury of nerve trunks, are not followed by much shock. Severe shock and subnormal temperature generally indicate hemorrhage. Therefore, as Dr. Dennis had remarked, severe shock is no contraindication for laparotomy.

In all cases in performing this operation it is necessary that the surgeon should surround himself with all the conditions which will tend to afford the patient the best possible chance of recovery. Dr. Bryant said, in conclusion, that there was one fact about which there was no doubt, and that was, that hemorrhage is a very important symptom, and that it is absolutely necessary that every bleeding point should be satisfactorily secured. Not infrequently the slightest oozing becomes changed to profuse hemorrhage as soon as the abdominal contents are returned to their places, and the cavity closed up. Experiments which he had made on dogs (shooting them in the abdomen, and then performing laparotomy) had further convinced him of the extreme importance of hemorrhage in gunshot wounds of the abdominal cavity.

Dr. E. G. Janeway said that the absence of hepatic dulness is a good general guide as to the existence of perforation of the intestines; but there are a certain number of cases which simulate this condition. Thus, in a case of typhoid fever under his observation, in which, on account of this symptom, perforation was supposed to have taken place, it was found at the autopsy that the resonance over the hepatic region was not due to this cause, but to the tilting of the liver. In regard to the operation of laparotomy, one possibility had occurred to him. Eberth, in his experiments on dogs, had found that by immersing the abdomen in a serum bath of 98° thrombosis and peritonitis could be prevented. Possibly, therefore, it might be advisable to operate on human subjects in the same way. It would hardly be safe to use bichloride of mercury as the antiseptic under the circumstances, but a warm saline solution might be employed for the bath.

Dr. J. W. S. Gouley said that he believed that the views expressed this evening were sound. The operation of laparotomy is justifiable when we have reason to believe that the hollow viscera have been injured. He then related two cases which had come under his own observation. The first was that of a young soldier twenty-two years ago, who suffered from a bayonet wound which passed completely through his body. It was not clear what organs had been injured in its course; but nothing was done, and the patient got well without a bad symptom.

The second case was one in which there was a pistol-shot wound which also passed completely through the body. It injured the right lobe of the liver and the lower lobe of the right lung; and bile, mingled with the pus, flowed freely out of both openings. In this case, also, recovery took place under the expectant plan of treatment. During the war he had, in fact, seen several cases which resulted successfully in a similar manner. At the same time, if he were to meet with such cases to-day, he did not hesitate to say that he should prepare himself to open the abdomen.

Dr. H. M. Biggs said that, in regard to the loss of liver dulness, he had met with a case which showed that this could not be relied upon as an infallible sign of perforation. The patient was suffering from peritonitis, and when the absence of hepatic dulness was detected, it was naturally supposed that perforation had occurred. There was no operation, and the patient died, when it was found at the autopsy that the cause of the resonance in the hepatic region was the fact that the intestines had forced themselves between the liver and the abdominal walls, and that no perforation had taken place.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, February 15, 1886.

The President, Samuel Nickles, M.D., in the Chair.

DIURETIC MEDICINES.

Dr. S. Nickles, in introducing the discussion of this subject, gave a brief description of the physiological action of the kidneys, sufficient to illustrate the mode of action of diuretics, as far as this has been ascertained. Some diuretics, he said, do not increase the secretion of urine in the normal state of the organism; but in certain forms of dropsy, especially those dependent upon heart disease, they display very remarkable power, often in a few days causing a very copious flow of limpid urine. On account of the abundance of the urine, they have been called hydragogue diuretics. It has been shown by experimental investigations that all such diuretics, in moderate doses, cause a more vigorous action of the heart, in consequence of which the blood-pressure becomes increased. Usually as soon as the blood-pressure approaches the normal, the urine increases. Hence their action is due not to any special influence on the secreting structures of the kidney, but to the increased general blood-pressure, which augments the velocity of the blood-flow in the kidneys. At the present time they are called indirect diuretics. They are indicated in all cases of dropsy in which the general blood-pressure is abnormally low, which is always the case in cardiac dropsy. They are contraindicated in all cases in which the blood-pressure is abnormally high, or in which the pulse is hard and tense. To this group of diuretics belong digitalis, squills, caffeine, apocynum, convallaria, adonis, and several others.

From the indirect diuretics must be carefully distinguished those medicines which increase the urine by a direct influence upon the secreting structures of the kidney—the direct diuretics. These augment the quantity of urine in healthy persons, although they cannot then produce a very abundant flow of urine. In certain forms of dropsy, however, they often cause a copious secretion. The action of these diuretics is attended by hyperæmia of the kidney. This was shown in certain experiments by Cohnheim and Roy, in which they injected urinary substances into the vascular system and carefully noted the changes produced in the volume of the kidneys. Uniformly the size of the kidneys became increased, showing an augmented quantity of blood in

the renal vessels. No increase of the blood-pressure in general resulted, and hence the dilatation of the arterioles of the kidneys was due to the greatly increased activitity of the renal epithelium, excited by the presence in the renal blood of urinary substances.

The hyperæmia produced by direct diuretics may become excessive, if very large doses are used. Thus oil of turpentine, copaiba, cubeb, cantharides, and others, may cause a very scanty flow of albuminous and bloody urine. Doubtless the flow of blood in the renal vessels becomes greatly retarded, and then, in consequence of nutritive changes of the epithelium and capillaries, other constituents of the blood, besides water, urea, uric acid, escape through the damaged structures.

The direct diuretics are contraindicated in all inflammatory diseases of the kidneys. They may be used in any form of dropsy, if the kidneys are healthy; but in cardiac dropsy are usually inefficient unless combined with the indirect diuretics. In some forms of kidney disorder the direct diuretics are effectual remedies; thus it is often observed that hæmaturia is quickly arrested by minute doses of oil of turpentine. On account of the severe disorder of the renal circulation which follows large doses of oil of turpentine, cubeb, copaiba, and cantharides, these remedies have been called stimulant or irritant diuretics. In diseases of the mucous membrane of the urinary passages produced by low organisms, copaiba, cubeb, and oil of turpentine are of decided utility. They render the urine aseptic, so that it does not easily undergo putrefaction. Hence it is supposed that their utility in catarrhal affections, and especially in gonorrhœa, is to some extent due to a destructive influence on the low organisms, and they have therefore been called antiseptic diuretics.

Not all the direct diuretics, when given in large doses, produce irritation of the kidneys. The saline diuretics, especially the acetate, citrate, and bitartrate of potassium, may be given in very large doses, especially if they are dissolved in much water. The action of all these salts is the same upon the kidney, which is readily accounted for by the fact that they are all converted into the carbonate of potassium in the blood. They are supposed to exert some effect upon the circulation and temperature in febrile diseases, and hence have been styled refrigerant diuretics.

Dr. Nickles did not propose to discuss the action of the special members of the groups of diuretics, or to point out the special indications for their therapeutic use; but he desired to call attention to a medicine, which, as yet, is little employed, but is of great utility in some forms of dropsy—namely, the resin of copaiba. Numerous careful observers have found that it often exerts a very decided diuretic action in cases of ascites, in which other diuretics are not usually very efficient. In a case of moderate ascites with œdema of the lower extremities, occurring in a patient with enlarged liver and jaundice, who had become very anæmic from profuse hæmatemesis, the resin of copaiba, in doses of about eight grains three times a day, in several days greatly increased the flow of urine, and in about two weeks caused the absorption of all the serum which had accumulated in the areolar tissue and peritoneal cavity.

DR. A. RAVOGLI called attention to the very important part the nervous system plays in the mechanism of this function. Some time ago he took part in a course of experiments on this subject. A large dog was curarized, the abdomen was opened and the ureters divided, and tubes inserted so as to collect the urine as it passed out. Acetate of potassium was then injected into the circulation. The flow of urine rapidly increased. Shortly after this the minor sympathetic nerve was cut. As a consequence the urine again rapidly increased in flow, so that it no longer dropped from the orifices of the tubes, but escaped in a small stream. The current from an electric battery was then passed through the divided ends of the nerve and the flow of the secretion was at once checked. When the battery was removed the urine again increased. This, the speaker believed, demonstrated the controlling influence of the sympathetic over the secretion of urine.

It is now know that albuminuria is sometimes present in cases in which there is no lesion of kidney structure. This is illustrated in the albuminuria of pregnancy. The balsam of copaiba acts largely upon the lesser sympathetic nerve, controlling the vasomotor circulation. This is shown by the fact that eruptions frequently follow its use. Such eruptions are the result, not of the irritant action of copaiba on the gastric mucous membrane, but of its action on the vasomotor nerves. While the balsam of copaiba is capable of producing this irritant action on the stomach, it manifests its action on other nerves also, and it is through its action on the splanchnics that it has its diuretic action.

DR. J. L. CLEVELAND reported a case illustrative of the proper use of the indirect diuretics in which the result was admirable. A patient had recently come to his office suffering from an aggravated attack of asthma, breathing with great difficulty; his lower limbs were œdematous, and the action of the heart was tumultuous. After he had examined the patient, he felt that he had a very unfavorable case before him and made a guarded prognosis. After a walk of only a few squares, the heart's action was so tumultuous as entirely to mask the valve sounds. He prescribed $\frac{1}{100}$ grain doses of digitalin. The next day, when he called on his patient he was astonished at the rapidity with which the remedy had acted. The heart had been toned up, its action was regular, its sounds distinct and a large amount of urine had been passed. The breathing was much more easy, and in a few days, with no other remedy, the trouble entirely disappeared. In proper cases there is hardly a remedy which will act with so great certainty.

DR. J. G. HYNDMAN did not believe that we can have an albuminuria without a lesion of the kidney. There are cases of albuminuria which are produced as a result of outside influences, as in the albuminuria of pregnancy referred to. In these cases the albuminuria is due to the pressure of the uterus or some of its appendages on the bloodvessels of the kidney, causing in it a passive hyperæmia, but it does not occur without alteration of kidney elements. A proof of this view with regard to the production of this form of albuminuria is seen in the numerous experiments that have been made, as by the ligation of the renal veins.

DR. RAVOGLI replied that his remark with reference to the albuminuria of pregnancy had been made in order to illustrate the fact that the occurrence of albuminuria does not of necessity imply the existence of a renal or cardiac disease. Of course, the albuminuria of preg-

nancy is a result of pressure, and consequent retardation of the blood-current, just as it is in the ligation of the renal veins.

Dr. R. W. Stewart raised the question whether the albuminuria of pregnancy is due to the pressure of the gravid uterus or whether there is not in reality a preëxisting disease of the kidneys in all these cases. It is a peculiar fact, he said, that albuminuria occurs in only certain cases of pregnancy and not in all, as it might be expected to do if it were the result of pressure.

Dr. Thad. A. Reamy stated that he had no doubt that albuminuria in a large number of cases is due to pressure. The fact of its occurring in only a certain proportion of cases can be accounted for by the fact that the pressure is not the same in degree in all cases of pregnancy. He added that he had recently seen cases of albuminuria in pregnant women cured within a few days by the administration of the muriated tincture of iron and the milk diet. Nowhere, however, have we a better illustration of the proper use of the indirect diuretics than in cardiac asthma, as in the case reported by Dr. Cleveland.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, February 19, 1886.

The President, T. G. Roddick, M.D., in the Chair.

UTERINE FIBROID.

Dr. Trenholme exhibited a large uterine fibroid which he had removed the previous week from a woman aged thirty-three. Patient, who was married and had borne children, had suffered from symptoms of fibroid for some sixteen years, and as the hemorrhages were becoming more severe had requested that an operation should be performed. Dr. Trenholme consented and performed the operation. The tumor was encircled by a wire écraseur one inch above the os uteri and removed; there was considerable hemorrhage which was difficult to control. The patient never rallied from the operation, but died seven hours after from shock.

SARCOMA OF SPLEEN IN A DOG.

Dr. Wyatt Johnston exhibited a specimen of angeio-sarcoma removed from a dog. The tumor weighed four pounds and was continuous with the upper end of the spleen substance. The dog suffered from abdominal dropsy, for which he was tapped, and died of peritonitis a few days subsequently.

LARGE URINARY CALCULUS.

The President presented a large uric acid calculus which he had recently removed from a man aged sixty-nine, by the lateral operation. The stone weighed three and one-quarter ounces. The patient had suffered from symptoms of stone for five years, and had been frequently sounded without result. The man recovered from the operation without a bad symptom.

DERMOID CYST.

Dr. Wm. Gardner presented two specimens, and briefly narrated the cases:

Case I. *Dermoid cyst containing a bunch of hair, two well-formed incisor teeth and one bicuspid tooth attached to a piece of bone, also a fourth tooth in another part of the cyst wall.*—The fluid contents contained a large quantity of fat, and on cooling looked like drippings of meat. The other ovary was an aggregation of cysts and was also removed. The patient, an unmarried lady of thirty, had noticed the tumor for only four months; she had had several attacks of pelvic pain in the side on which was the tumor. She made a rapid and easy recovery, leaving for home on the eighteenth day.

Case II. *Tait's operation.*—Uterine appendages removed from a case of uterine myoma. Both ovaries consisted of a mass of smooth cysts and were three times the normal size. The tubes were healthy. The myoma was as large as a child's head. The patient had been married three years and had never been pregnant. She was much blanched by hemorrhage and watery discharges which had lasted for five years. She had suffered from fever, abdominal distention, and profuse metrostaxis after the operation, but at the date of the meeting (eleventh day) was doing perfectly well.

MALIGNANT STRICTURE OF THE ŒSOPHAGUS.

Dr. George Ross showed a specimen of cancer of the œsophagus, the following being the principal facts in the clinical history: A man æt. fifty-four, six feet four inches high, and who had been immensely powerful, was admitted into the hospital with intense dysphagia and in a state of great emaciation and weakness. There was an intense fetor of breath, and he had had a severe cough for some time with a copious similarly fetid purulent expectoration. He was intemperate and was in the habit of drinking raw spirits. The difficulty of swallowing had gradually developed during more than a year, until of late even fluids were forced down with the greatest difficulty and straining. There had never been any vomiting or regurgitation of food. An œsophageal bougie of soft, flexible rubber and of almost the largest size, was twice passed its full length without meeting with any special obstruction. It slid down with ease and not the slightest force was used. The withdrawal of the bougie was followed by the escape of horribly foul air from the patient's mouth, and the instrument itself was smeared with stinking pus. Physical examination of the chest gave signs of cavity in left apex and of softening deposit with cavity localized in right mammary region. He rapidly became enfeebled and died in about a month from asthenia, continuing to the end to swallow a large quantity of fluids every day, and there was never seen any regurgitation. The diagnosis had been epithelioma of the œsophagus involving the tube in such a way as to produce all the phenomena of stenosis and yet permit of considerable patency of the lumen; secondary cancer of the lungs with gangrene. The autopsy showed an epithelioma of unusually firm texture situated just below the level of the cricoid cartilages and extending for about two inches. It encircled the œsophagus and the stricture was almost impermeable. It was only after repeated efforts that a No. 2 flexible (urethral) catheter could be insinuated through it. In the apex of the left lung was a large cavity containing a considerable slough lying loose within it—the chamber was excessively fetid. The upper part of the lung was firmly adherent to the diseased portion of the œsophagus, but *no communication* could be shown between the pharynx and the apex-

cavity. In the front of the right lung was a mass of cancer which had softened centrally.

Dr. Ross directed attention to some points of the case. He thought the disease might here have originated from the habit of drinking copiously of raw spirits. The absence of all regurgitation was a remarkable feature, considering the high situation of the growth and the tightness of the stricture. He also asked the question: "What course was taken by the bougie?" The tight, firmly organized stricture must have existed for a long time; such a large instrument could not possibly have passed through within two or three weeks of the man's death. The bougie was too large, the space too narrow, and the stricture too high for it to have bent upon itself. Could it have passed into the cavity in the apex of the lung? If so, there must have existed a direct and free communication with this part from the pharynx, which avenue had been subsequently shut off by adhesive inflammation. Except on the latter hypothesis, he was at a loss to explain the facts given above.

MALIGNANT DISEASE OF RECTUM TREATED BY EXCISION AND COLOTOMY.

Dr. George E. Fenwick read a paper on the operative treatment of malignant disease of the rectum, with cases. He began by remarking that the origin of cancer is still an unsolved mystery. He said that some look upon cancer as being at first a local disease, produced by long-continued irritation or accidental injury. The disease begins at one point while the rest of the body is apparently healthy. They believe that the constitutional implication is secondary to the local disease, as cancer first spreads by infiltration of the structures in its immediate neighborhood, and when the lymphatics are involved is distributed to all parts of the body. Others, again, assert that certain people are predisposed to cancer, and that without the predisposition no amount of local injury or irritation will produce this disease.

Dr. Fenwick thought that in many cases the disease was of purely local origin, but that in some there was an hereditary predisposition. He regarded it as more than a mere coincidence that many members of the same family are occasionally affected, and that it may show itself in several generations. He held, however, that if it could be shown that cancer could be arrested by early surgical removal without subsequent recurrence, the position of the localists would be much strengthened. If there is a time when cancer is purely local, the necessity for early surgical interference becomes imperative. Although recurrence is the rule after the extirpation of cancerous growths, still cases do occasionally occur in which no recurrence is observed, and some of the cases related by the reader of the paper bore evidence to the truth of this statement.

Cancer of the rectum arises in a very insidious manner, and in many cases it is almost impossible to obtain a correct clinical history regarding the length of time the disease has existed. The earliest symptoms are, smarting, itching, and general discomfort about the rectum, after defecation and exercise there is a dull aching pain more or less constant. The patient's rest is broken and his general health in consequence suffers. As the disease advances defecation becomes more difficult and painful, the bowel is never properly emptied, and blood is frequently passed. If not relieved by operation, the patient rapidly fails and dies of exhaustion. The duration of the disease is from eight months to three or four years. Dr. Fenwick went on to remark that if the disease is low down, early extirpation should be practised, and that as one could get above the seat of the disease, excision should be performed in preference to the palliative operation of colotomy. The operation of excision, though often difficult, was not dangerous, and often relieves the patient for years. In women the operation is much easier than in men on account of the roominess of the pelvis and the presence of the vagina, enabling the operator more easily to reach the disease. In most of the cases he had sacrificed the external spincter, but after a time the patient had considerable retentive power. In his last case he preserved the external sphincter, with benefit to the patient.

Case I. *Excision of rectum.*—Patient a woman, æt. fifty-eight, who had a cancerous ulcer near the external sphincter, about the size of a half-dollar. The disease had existed several months. The spincter was involved. No enlarged glands could be made out. Excision advised and operation performed in May, 1876. A circular incision was made round lower end of bowel, at some distance from edge of growth, and the lower two inches of the bowel dissected away. There was considerable hemorrhage and the vessels were tied separately. The bowel was removed with the knife. Patient had no recurrence and died some three years ago.

Case II. *Colotomy.*—Girl, æt. twelve, came to hospital January, 1876, for what was thought to be syphilitic disease of rectum. Nodular condition of bowel as far as finger could reach. Antisyphilitic treatment of no avail. The disease increased and the nodules became ulcerated. The bowel becoming much obstructed, lumbar colotomy was performed with great relief to patient. The patient recovered well from the operation, left the hospital in a few weeks, and was lost sight of.

Case III. *Colotomy.*—Mr. L. æt. sixty-two, French Canadian, admitted to hospital Nov. 7, 1877. Had for years suffered from piles, for which he had been treated some twelve years before by the application of nitric acid. About end of previous June began to have pain in the rectum, which was greatly increased on going to stool. Defecation had lately become difficult and relief could only be obtained by tepid water injections. On examination a huge growth was found obstructing the bowel near its lower end, the finger could not be passed above it. Lumbar colotomy performed. Easy and rapid recovery; patient much relieved, and lived in comparative comfort till the following June, eight months.

Case IV. *Excision of rectum.*—Mrs. N., seventy years of age, consulted Dr. Fenwick for what she supposed to be dysentery. She had great tenesmus and a large mass of the bowel protruded. On examination a cancerous mass was seen involving the entire circumference of the anus and extending up the anterior wall of the bowel for some two inches. As the finger could easily reach above the mass, excision was advised. The operation was performed August 6, 1878. Three and a half inches of the bowel were removed, together with the external sphincter. The patient made a good recovery. This old lady died on April 10th of last

year (1885), having lived six years after the excision. The cancer never returned; patient died of some heart affection.

Case V. *Excision of rectum.*—Mr. A., farmer, æt. fifty-six, consulted Dr. Fenwick, Jan. 1880, for what he supposed to be piles. Had suffered for the last five months. On examination a cancerous mass was found a little above the anus, extending completely round the bowel, more of the mass being in the anterior portion. The finger could easily be passed beyond the disease. Operation January 22, 1880. Nearly four inches of bowel removed. On separating the bowel from the tissue of the bladder, the right vas deferens was cut. There was not a great deal of hemorrhage. The external sphincter was removed. After cutting away the diseased bowel the healthy bowel was brought down and stitched to the anus. In both these last cases the posterior wall of the bowel was incised as far back as the coccyx before removal. The patient rapidly recovered and lived in comparative comfort for three years, when the disease returned high up and patient became rapidly emaciated and died.

Case VI. *Excision of rectum.*—Man, æt. sixty, admitted to hospital June, 1882, with cancer of anterior wall of rectum a little above the anus. Excision performed, but great difficulty was experienced in separating the bowel from the prostate gland and bladder, which were found to be involved in the disease. A portion of the bladder was removed with the bowel. The patient died of exhaustion four days after the operation.

Case VII. *Excision of rectum, and colotomy.*—Man, æt. forty-five, consulted Dr. Fenwick in November, 1883, for a bleeding tumor of the rectum. He had for several years suffered from "rectal disease," which was thought to be piles, for which he had taken all the advertised quack remedies. On examination a fungoid mass with a hard base was found in the posterior wall of the rectum. It extended up the bowel a couple of inches and involved almost one-third of the circumference of the gut. Excision advised and the operation performed November, 1883. There was considerable hemorrhage and the bowel was ligatured before removal. The patient's recovery, owing to loss of blood, was slow. The tumor was examined by Dr. Osler and pronounced to be a well-marked case of villous tumor. Patient did well for about a year, when he began to have considerable trouble with his bowels—had great difficulty in relieving himself. On examining him it was found that the disease had returned and was now distinctly epitheliomatous. Excision was again advised, and another operation performed in January, 1885. About four inches of the bowel were removed and some glands which were involved. The patient recovered rapidly and returned to his business, but the disease again returned higher up, and symptoms of obstruction appearing, colotomy was performed in July, 1885. This relieved him, but he gradually sank and died early in the present year (1886).

Case VIII. *Excision of rectum.*—Mrs. S., æt. forty-two, consulted Dr. Fenwick for some affection of the rectum for which she had suffered for the last six months. Was troubled with painful and difficult defecation and passed imperfectly formed feces. On examination, found a cancerous ulcerated growth about as large as a penny on the anterior wall of the bowel one inch above the anus, beyond this several large glands could be felt. Excision advised and operation performed on the 3d of February, 1886. The whole bowel was removed and the external sphincter preserved—about three and a half inches taken away. Diseased glands all removed. The end of the healthy bowel was brought down and stitched to the anus. In separating the anterior wall of the rectum from the vagina, the latter structure was torn slightly, but the rent was immediately sutured. The peritoneum, where the parts between the bowel and vagina were separated, prolapsed into the wound but was not wounded. The patient rapidly recovered, and when last seen had good retentive power.

In operating, Dr. Fenwick remarked that after the first incision he chiefly used his fingers to separate the bowel from the surrounding structures.

CORRESPONDENCE.

EXTRAUTERINE CHANGED TO INTRAUTERINE PREGNANCY BY ELECTRICITY.

To the Editor of The Medical News.

Sir: In this age of ohms, ampères, and volts, scepticism as to the power of electricity is in the highest degree unreasonable—not to say reprehensible. If electricity, transported thirty-five miles by telegraph wire, can move an ordinary locomotive engine from one place to another, surely the same power can cause an embryo to move a few inches along the *Chemin de Fallopius.*' It would appear so to Doctors Garrigues, Mundé, and Stabler. Upon the communication of the last-named gentleman in The Medical News of Feb. 27, I should like to make just two criticisms.

1. The patient was delivered of a four months' fœtus on the 13th of December, and on the 18th of November—within a month—the sound had been passed into an apparently normal uterus, to the interior of which applications of iodine and nitrate of silver were made. It is, I believe, invariable in cases of extrauterine pregnancy for the uterus and its mucosa in the early months to undergo a development proportionate in some degree to the growth of the ovum. The decidua vera may form a velvety, highly vascular layer a quarter of an inch in thickness. In the cases of extrauterine pregnancy which I have dissected, this enlargement has always been present, and it was beautifully shown in several specimens recently exhibited by Dr. Formad, at the Philadelphia Pathological Society.

2. We are asked to believe that some time between Dec. 4th, the date of the last application of galvanism, and Dec. 13th, the date of delivery, the embryo was transferred from the tube into the uterine cavity, and it is suggested that the hypertrophied walls of the tube under the stimulus of electricity effected the removal.

That it could have been a pure tubal pregnancy seems unlikely from the age which the ovum had attained, and from the very perfect state of placenta and appendages. So far as we have observed, there is in these cases *thinning*, not hypertrophy, of the muscular coat of the tube. If within the proximate end of the tube, surely there would have been, at the middle of the third month, considerable enlargement of the uterus.

I am, yours, etc.,

E. Y. D.

NEWS ITEMS.

CHICAGO.

(From our Special Correspondent.)

Rush Medical College.—The forty-third annual commencement exercises of Rush Medical College occurred on the 16th instant. One hundred and fifty-six students received the ordinary degree of Doctor of Medicine. Five gentlemen received the honorary degree, namely, Drs. D. A. Huffield and W. M. Hanna, of Illinois; Dr. Hoeber, of Hamburg, Germany; Dr. J. A. Standiland Grant, of Cairo, Egypt; and Dr. Daniel Hack Tuke, of London.

About 410 students have been in attendance upon the College during the past term.

In the evening of the 16th, at the Palmer House, the Faculty of the College gave a banquet to the alumni, over four hundred of whom were present.

Hereafter students in this College must, in order to graduate, take a special course in the Laboratory of Physiology and Pathology. The Laboratory has been prepared for this work and Dr. A. J. Ochsner, of Wisconsin, has been appointed Demonstrator in this department. The course will consist of fifteen or more lessons, which will be devoted to the study, with the microscope, of normal and morbid specimens of tissues; of urinary sediments, sputa, microörganisms, etc.

A Post-Graduate Medical School has been organized to combine the clinical and practical laboratory teaching of Rush College, the clinical work of the Central Dispensary of West Chicago, the Presbyterian Hospital, the Eye and Ear Infirmary, and, to some extent, the Cook County Hospital. The sessions of the school will probably occur in June, July, and August, and take the place of the Practitioners' Course which has heretofore been carried on each spring by Rush College. It is not expected that any didactic lectures will be given, but that the teaching will be practical and clinical entirely. An announcement of the school will be issued in the near future.

Cooking for Invalids.—The importance now attached to diet in the treatment of disease necessitates especial care in the preparation of food for invalids. Physicians are aware that such preparation is practically impossible to the ordinary cook in a private family, not only because she has no time apart from her regular duties, but because she is, as a rule, unwilling and incompetent to work by weight and measure, watch and thermometer. Especially is this the case with the partially pre-digested foods, which a labor-saving cook can easily make to seem right, while they are in fact valueless. It is also difficult, even for trained nurses, from their lack of general experience in cooking, which cannot be supplied by the few lessons they may receive while under training.

To meet this difficulty, the New Century Guild of Working Women, 1131 Girard Street, Philadelphia, offers to prepare and deliver to order all kinds of foods prescribed by physicians, including all forms of pre-digested nourishment.

The New Century Guild is a branch of the New Century Club, whose name is sufficient guarantee of its conscientiousness in its undertakings.

The German Medical Congress.—The fifth Congress "*für innere Medicin*," will take place at Wiesbaden from April the 14th to the 17th, under the presidency of Dr. Leyden, of Berlin. The programme of papers and discussion is as follows: At the first sitting, Wednesday, April 14th, the Pathology and Therapeutics of Diabetes Mellitus, introduced by Drs. Stokvis (Amsterdam), and Hoffman (Dorpat); second sitting, Thursday, April 15th, the Operative Treatment of Pleural Exudation, Dr. Fräntzel (Berlin), and Dr. Weber (Halle); third sitting, Friday, April 16th, the Therapeutics of Syphilis, Dr. Kasson (Vienna), and Dr. Neisser (Breslau). Other communications will be made on Antipyresis, by Dr. Riess, of Berlin; on Ptomaines, by Dr. Brieger; on Blood-pressure in Morphia-narcosis, by Dr. Fick, of Würzburg, etc.

H. J. Bigelow, M.D., has resigned his position as surgeon to the Massachusetts General Hospital. His resignation has been accepted by the Trustees, and he has been made Surgeon Emeritus, with five beds placed at his disposal.

Another Student for Pasteur.—It is announced that the city of Amsterdam will send Dr. Saltet, of the hygienic laboratory, to Paris, to study M. Pasteur's methods of inoculation for rabies. The expenses will be paid by the municipal funds.

The Fifteenth Congress of the German Surgical Society will be held in Berlin, from April 7th to 10th. Among the subjects put down for discussion are: tuberculosis (continued); the results of operation on complicated harelip; operations on the urinary bladder, including high and median lithotomy. Information may be obtained from Professor Gurlt, Bernburger Strasse, 15–16, Berlin.

Extirpation of the Kidney.—On Monday, February 1st, at the London Hospital, Mr. Frederick Treves removed from a woman, aged thirty-five, the left kidney, together with both ovaries—the kidney for hydronephrosis, the ovaries for multilocular cystomata. The patient, we understand, is doing remarkably well.

Dr. Luchsinger, Professor of Physiology in Zurich, has died at Meran. It is expected that Dr. Gaule, who has been lecturing for him, will be elected.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING FEBRUARY 27, 1886.

Clark, J. H., *Surgeon*.—Detached from the "Hartford," on the reporting of his relief, Medical Inspector Bradley.

Bradley, Michael, *Medical Inspector*.—Ordered by steamer of March 10 from New York to Aspinwall, thence to Panama, and to the "Hartford," as the relief of Surgeon J. H. Clarke.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 23 TO MARCH 1, 1886.

Spencer, Wm. G., *Captain and Assistant Surgeon*.—Ordered for duty at Fort Yates, Dakota Territory.—*S. O. 17, Department of Dakota*, February 23, 1886.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLVIII. SATURDAY, MARCH 13, 1886. NO. 11.

ORIGINAL LECTURES.

THE ETIOLOGY, MORBID ANATOMY, VARIETIES, AND TREATMENT OF CLUB-FOOT.

Two Clinical Lectures delivered at the Philadelphia Hospital.

BY A. SYDNEY ROBERTS, M.D.,

SURGEON TO THE HOSPITAL, AND ORTHOPÆDIC SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE UNIVERSITY HOSPITAL; INSTRUCTOR IN ORTHOPÆDIC SURGERY IN THE UNIVERSITY OF PENNSYLVANIA, ETC.

LECTURE I.

GENTLEMEN: Every observant person, whether within or without the profession of medicine, must be impressed with the prevalence of various deformities in individuals of the human family, and their very existence must cause him to reflect upon the causes of their being, their chronic and progressive nature, and the apparent difficulty of arresting them. Much of this has been due to lack of knowledge of the mechanical factors which enter into their etiology, and the very general neglect the subject of malformations has received, from an educational standpoint, in our medical schools. Though twenty-five years have elapsed since the establishment of orthopædic surgery as a legitimate special branch of surgical art, its science and practice, noticeably in this city, are permitted to occupy a very subordinate position, and its principles are practically untaught. In this clinic, which will initiate the course of lectures upon orthopædic surgery in the Philadelphia Hospital, which it will be my privilege to deliver before you this Spring, no better subject could be chosen than one descriptive of *club-foot*, a condition which you will frequently meet in practice, and of which many examples may be constantly observed in the nervous, obstetrical, and surgical wards of this hospital.

We may define club-foot, or talipes, which latter designation was first employed, about thirty years ago, by William J. Little, of London, as a deformity of the foot; caused by paralysis, permanent spasm, or structural shortening of the muscles, contractions of fasciæ or ligaments, which result in an alteration of the normal relations of the tibio-astragaloid articulation, or between the bones of the tarsus proper. Under the generic term club-foot, or talipes, we include all deformities of the foot which occur on an antero-posterior or transverse plane, and which are characterized by flexion, extension, inversion, or eversisn.

To obtain a clear conception of the deformities under consideration, it is best to divide the foot into an anterior and a posterior portion, the former, the "*pes*," or foot proper, and the latter, the "*talus*," or ankle. These portions articulate at Chopart's joint, which is formed by the astragalus and os calcis behind, and the scaphoid and cuboid in front. For purposes of clinical study, club-foot is most conveniently separated into two classes, composed of the simple and the compound forms. Of the former there are four varieties, two between the tibia and foot, namely, *equinus*, in which the heel is raised, the foot being held in the extended position, the patient walking upon the ball of the foot; and *calcaneus*, its opposite, in which the patient walks upon the heel, the foot being drawn into the position of flexion. There are also two lateral deformities: *varus*, in which the internal border of the foot is elevated, the sole directed inward, and the anterior portion of the foot adducted; and *valgus*, its opposite, in which the outer side of the foot is raised, and the sole everted. Any combination of these simple varieties will present compound forms, such as *talipes equino-varus*, *equino-valgus*, *calcaneo-valgus*, etc.; some authors have added others: for instance, *talipes cavus*, in which the arch of the foot is increased, and *talipes planus*, or spurious valgus. in which the foot is flattened, the arch resting upon the ground. Recently, Shäffer, of New York, under the title "*non-deforming club-foot*," has described a class of cases in which there is little or no deformity, but which are very important on account of the inconvenience they occasion the sufferer, and the results to which they give rise, coupled with the liability of being overlooked, unless care be taken in the examination of the patient.

The varieties of club-foot may be classified as follows:

TABLE No 1.

- Varieties
  - Simple
    - Antero-posterior
      - Equinus.
      - Calcaneus.
    - Lateral
      - Varus.
      - Valgus.
  - Compound
    - Equino-
      - Varus.
      - Valgus.
    - Calcaneo-
      - Varus.
      - Valgus.
  - Other forms
    - Cavus.
    - Planus.
    - Non-deforming.

As previously mentioned, these simple forms, or their combinations, constitute the deformities which you will meet with, and a knowledge of their relative frequency is of interest and importance. Much difficulty is experienced in the investigation of this subject, owing to the difference in nomenclature employed by various authors, similar conditions being spoken of under different names. Duval has recorded 1000 cases, of which 574 were congenital; 364 of these were in males, and 210 in females. His statistics as to relative frequency are valuable, and are as follows:

TABLE NO. II.

	Cases.	Boys.	Girls.
Equinus and equino-varus	417	215	202
Varus	532	302	230
Valgus	22	14	8
Calcaneus	9	6	3
Extreme calcaneus	20	13	7
Totals	1000	550	450

I have compiled the following statistics, shown in Table No. III., from the records of the New York Orthopædic Hospital, and the Orthopædic Dispensary of the University of Pennsylvania:

Table No. III.

	Congenital	Acquired.
Equinus	5	87
Calcaneus	3	31
Varus	73	66
Valgus	29	236
Equino-varus	95	68
Equino-valgus	3	9
Calcaneo-varus	0	2
Calcaneo-valgus	5	34
Totals	213	533

Lannelongue has collected the statistics of the Maternity Hospital (Paris), covering a period of ten years, from 1858 to 1867, inclusive. In 15,229 births, 8 children were born with club-foot, a proportion of about 1 case in 1963 births.

The condition may be present as a congenital or an acquired deformity, and the relative frequency of the two forms may be seen by reference to Table No. III., from the cases treated in the New York Orthopædic Hospital and the Orthopædic Dispensary of the University of Pennsylvania, in which are recorded 746 cases, of which 213 were congenital, and 533 acquired. Tamplin's deductions shown in Table No. IV., covering 764 cases of congenital talipes, show the relative frequency to be as follows:

Table No. IV.

Congenital.	
Talipes varus	688 cases.
" valgus	42 "
" calcaneus	19 "
" varus of one foot and valgus of the other	15 "
Total	764 "
Acquired.	
Talipes equinus	401 "
" valgus	181 "
" equino-varus	162 "
" calc. and calc.-valgus	110 "
" equino-valgus	80 "
" varus	60 "
" varus of one foot and valgus of the other	5 "
Total	999 "

Adams states the proportion between the congenital and acquired forms to be as 2 : 3, and the tables already referred to show the large preponderance of cases in which the deformity has been acquired. Giving due weight to the statistics which have been alluded to, we may conclude that club-foot occurs more frequently in males than in females; that cases in which inversion and adduction of the foot, either accompanied or not by elevation of the heel, or the varus types, are oftener met with, and that the right foot is more frequently deformed than the left, but that many more cases of double club-foot occur than of single; and that the primitive forms, pure equinus, calcaneus, varus, or valgus, are rare.

The etiology of congenital talipes is veiled in obscurity. The difficulty of studying pathological changes occurring during intrauterine life is self-evident, as the fœtus cannot be subjected to any direct scientific method of investigation. Comparative physiology, embryology, and the changes and diseases which occur subsequently to birth give us data of comparative value, but all such investigations have resulted in much speculation, many theories, and but few facts. The theory that diseases which produce the acquired forms have their prototypes during intrauterine existence has its supporters, notably Little. But microscopical research has not yet shown the existence of changes in the fœtal brain and spinal cord analogous to those found in cases of the acquired paralytic forms. Voluntary muscular control is retained in congenital cases, while it is lost in the acquired varieties referred to, and the electrical reactions are markedly different; so that this theory has no foundation to rest upon, except the similarity in the appearance of the deformities.

Hereditary influence, with its transmission of peculiarities of face and form, of various tendencies, of traits of character, etc., has some weight as an etiological factor.

Another theory of causation is that of arrest of development, and although cases occur in which coexisting deformities, such as spina bifida, harelip, cleft palate, etc., are also present, the feet show no evidence of arrest of development, the only alteration being that of the direction of the planes of the feet which is characteristic of the deformity. Adams and Hüter, it is true, have described changes in the bones involved, consisting of alteration of form and relative position of articulating facets, but these changes are by no means constant, and whether they be causative or secondary to the altered relation of the bones, is a matter regarding which there is much difference of opinion. Personally, I incline to the latter view, although the theory has many eminent supporters, including A. Lücke.

The theory which has, perhaps, the greatest number of votaries, is that which ascribes to abnormal intrauterine pressure, and deficiency of amniotic fluid, the influence productive of club-foot; the foot being permanently fixed in the abnormal position during intrauterine life. Although numbering among its supporters such names as Volkmann, Kocher, Banga, and Parker, I do not think the assumption tenable, for the following reasons: Were this deformity the result of pressure, it is reasonable to believe that in many cases deformity of other members would coexist, having been exposed to the same pressure-influence; such, however, is not the case, combinations of this kind being of rare occurrence. Again, in children who have been born with club-foot, and in which the mother had previously given birth to several healthy children, no appreciable difference in the quantity of amniotic fluid discharged during the various labors can be made out. Further, I have recently seen a case of double equino-varus in a twin, the other child showing no deformity whatever.

Dr. H. W. Berg, of New York, in a series of investigations which are commendable for their originality, ascribes congenital equino-varus to a failure of rotation during intrauterine existence. In his studies at the New York Hospital and Wood's Museum at Bellevue Hospital, he has followed the changes which occur in the position of the lower extremities at different periods of fœtal life. At first, the entire leg is rotated outward, and the feet are in a position of marked varus, and,

subsequently, of equino-varus. Later, rotation inward takes place, gradually diminishing the amount of varus; but even after this rotation has been completed, some varus remains, and, in a very slight degree, is the normal position of the foot in the newborn. Dr. Berg found, in some instances, equinus to be present in fœtuses of two, three, and four months, the condition disappearing in the process of normal growth, and he reaches the conclusion, that in early fœtal life equino-varus or varus is physiological, and that its disappearance is coincident and keeps pace with the normal rotation of the limb. When, from any cause, rotation is retarded or arrested, club-foot results.

To summarize the theories to which I have alluded, and which constitute the principal ones advanced in explanation of the causes of congenital talipes, I have reduced them to the following: that which would ascribe club-foot to pathological changes occurring in the fœtus, similar to post-natal diseases; that which assumes as a cause, the action of mechanical forces upon the child in utero; then the theory of heredity, with its influences but little understood; the theory of arrest of development; and, lastly, the theory promulgated by Dr. Berg, which would make club-foot dependent upon the absence or retardation of rotation. The last mentioned possesses the merit of being demonstrable by embryological research, and in the present state of our knowledge it has, in my opinion, greater claims to recognition than those which are based upon similarity of post-natal conditions, or those which rest upon even a more fanciful basis.

Turning our attention now to the consideration of the etiology of acquired talipes, we do not find the path of investigation beset with the difficulties we met with in the study of the causation of the congenital types. We may divide the causes into six groups: 1st. Infantile spinal paralysis. 2d. Spastic contractions due to an irritative lesion of the spinal cord. 3d. Contraction of aponeuroses. 4th. Traumatism. 5th. Rachitis. 6th. Hysteria.

By far the greater number of cases of acquired talipes are due to infantile spinal paralysis—"poliomyelitis anterior." This is essentially a disease of childhood, usually occurring at the period of dentition, its invasion being, as a rule, sudden, marked by fever, gastro-intestinal disturbance, sometimes ushered in by a convulsion, and immediately followed by muscular paralysis, more or less extensive. Recovery follows rapidly in many of the muscles affected, but is rarely, if ever, complete, a certain amount of residual paralysis remaining permanently, in one or both of the lower extremities. Atrophic changes now take place, and are characterized by wasting of the muscles of the limb, loss of electro-contractility, especially to the faradic current; later by reactions, when stimulated by galvanism, characteristic of degenerative change, and deformity, of which the most frequent is club-foot.

It has been thought that the deformity in these cases was due to the loss of equilibrium between the muscles of the limb; one set being paralyzed, their antagonists drawing the foot into the deformed position; but Hüter has shown that the weight of the limb, in the position assumed in paralysis, is the cause of contractions, and that these were due to atrophy and arrest of growth, and were not in any sense muscular. In some cases, resulting from poliomyelitis, the deformity is due entirely to the force of gravity, the foot dropping into the position of equinus, and the anterior portion being adducted by its own weight. In these cases there is little if any contraction, and the deformity is readily reduced by manual pressure, but, of course, returns immediately upon the removal of the hand. Volkmann, also, has directed attention to the fact, that owing to the weight of the body, the limb assumes an abnormal position, which eventually becomes permanent, being due, not to contraction, but to abnormal growth.

The "spastic paralysis" of Erb is also productive of club-foot. This condition has been called by Adams "paralysis with rigid muscles," and by Seguin, "tetanoid paraplegia." It is well illustrated by the case that I now present.

Case 1. *Tetanoid Paraplegia, producing double Talipes Equino-varus.*—Barney, æt. six years. No record or information could be obtained regarding previous history. Having stripped him, it will be noticed that the thighs are adducted and slightly flexed upon the pelvis. The legs are held firmly at a moderate degree of flexion at the knee-joint. The feet are extended and inverted in the position of pronounced equino-varus. All muscular groups of the lower limbs are in a condition of spasmodic rigidity. You will notice these contractions may be temporarily overcome by firm and continuous pressure, but immediately reappear upon the removal of the opposing force. Locomotion, with assistance, is accomplished with difficuly by a swinging, discordant gait, typical of the disease, the patient walking only upon the ball of the feet and toes, the weight of his body not being sufficient to overcome the contraction and bring the heels to the floor. The other symptoms characteristic of the central lesion—deficient intelligence, strabismus, exaggerated muscular reflexes, and general rigidity and spasm of the muscular system, are all present. As I propose to operate upon this patient, I will defer a further consideration of his *feet* until my next clinic. The condition appears to be due, in some instances, to retarded development in the motor tract of the brain; in others, to a lesion in the same position, followed by secondary changes in the lateral columns of the cord. The researches of Rupprecht, of Dresden, not only show that tenotomy is followed in some of these cases by improvement in the position of the feet, but that the mental state is also appreciably benefited by the operation. His article has been published in Volkmann's series of clinical lectures, and constitutes an important and valuable contribution to our knowledge of this interesting class of cases. Various spinal diseases, acute compression, syphilis, tumors, caries, etc., are frequently productive of a similar condition. Other diseases of the nervous system should be mentioned as causes of club-foot. In rare cases, pseudo-hypertrophic muscular paralysis, and post-hemiplegic contractions produce the deformity, but neuromimetic conditions, which of late years have attracted much attention, are more frequently the cause of it. A careful elimination of other possible etiological factors in a given case, coupled with a proper appreciation of the general condition, will usually lead to correct conclusions in cases of the latter kind.

Sayre has advocated the view, that paralysis due to reflex irritation is, in many instances, productive of

talipes, and has reported cases in which he claims that functional disturbance of the nervous system can cause spasm of muscles, which, if sufficiently prolonged, while healthy growth continues in their antagonists, becomes the cause of a permanent deformity. Much discussion has taken place concerning this condition as a cause of club-foot, but I do not consider that Dr. Sayre's theory is in any way tenable.

Talipes equinus sometimes occurs as a concomitant of the paraplegia of Pott's disease of the spine, but disappears upon recovery from the paralysis; joint diseases of the lower extremity are also potent factors in the production of club-foot. In ankle-joint disease the deformity may follow disease of the articulation, and remain as a permanent condition due to ankylosis of the joint in the position of extension. In hip-joint disease, it would be due to prolonged malposition during the period of growth. I have lately seen a case of this disease in which the limb upon the affected side was shortened but one inch, and in which there was a marked equinus accompanied by contraction of the plantar fascia. Occupations requiring long-continued standing in one position can be also considered causative agents; printers, bakers, blacksmiths, and those engaged in kindred trades may be mentioned as the principal sufferers. The enforced position and the weight of the body are the factors in the production of this variety of the deformity, which is most commonly a valgus. The same remarks will apply to the valgus of adolescence, due probably to rapid growth, and increased weight of the body, without, however, a corresponding development of the muscles, aponeurosis, and ligaments of the feet. The influence of long-continued decubitus is further shown by the case reported by Volkmann, in which an equinus was found, after prolonged typhoid fever, so resistant that it required a year's treatment to restore the feet to their normal position. As to traumatism, it will be only necessary to allude to the possibility of wounds, burns, rupture of tendons, etc. The former may result in the production of deep cicatrices, which by their contraction tend to draw the foot into a deformed position. Spurious valgus or splay-foot is frequently the result of rachitis, although, as before mentioned, occupation is often an important factor in its causation. All these forms may be simulated by hysteria, and this class of cases frequently taxes the knowledge and ingenuity of the surgeon; their recognition lies in a thorough understanding of general morbid conditions and a careful diagnosis by exclusion.

Before closing, I desire to call your attention to the morbid anatomy of club-foot. I shall, however, touch upon it only sufficiently to give you an idea of the muscles involved in the production of the various deformities and will illustrate my remarks by reference to the following classification.

TABLE NO. V.

Extension (equinus)	Gastrocnemius. Soleus. Plantaris. Peroneus longus.
Flexion (calcaneus)	Tibialis anticus. Peroneus tertius. Extensor longus digitorum.
Adduction (varus)	Tibialis anticus. Tibialis posticus. Flexor longus digitorum.
Abduction (valgus)	Peroneus longus. Peroneus brevis. Peroneus tertius.

Dividing the muscles into three groups, which move the foot in four directions, as shown in Table No. V., we have a posterior group, the calf muscles, the gastrocnemius, and the soleus, and two anterior groups, the tibial and the peroneal. In the normal condition, an equilibrium is maintained between these muscles, and the correct anatomical relation of the parts is preserved; but should spasmodic contraction or paralysis of one or more of these groups occur, the balance is destroyed, and deformity takes place. As has been remarked, the purely primitive forms of club-foot are extremely rare, and this statement will apply to these deformities, whether they be congenital or acquired. A brief consideration of them, however, is necessary in order that a clear understanding of the compound forms which are encountered most frequently in practice may be obtained. They are *equinus*, *calcaneus*, *varus*, and *valgus*; the two former being antero-posterior deformities; the two latter occurring upon a transverse plane.

In *talipes equinus* the heel is raised, the patient walking upon the ball of the foot. Here we find the posterior group of muscles, consisting of the gastrocnemius and soleus contracted and shortened, the tendo-Achillis being felt as as a tense band. In the opposite condition, *talipes calcaneus*, the anterior groups of muscles, tibialis anticus, posticus, and peronei, are at fault, and being shortened, maintain the foot in the position of flexion, the patient walking upon the heel. *Talipes varus* manifests itself by inversion and adduction of the foot, the deformity taking place anterior to Chopart's joint; in it, the sole is turned inward and raised, and the anterior portion of the foot adducted, the tibialis anticus and posticus and flexor longus digitorum being contracted. In *valgus*, on the contrary, the sole is turned outward, and its outer border raised, the peronei being the muscles at fault. In this deformity, however, the plantar fascia is involved, the arch of the foot being diminished by its relaxation.

In all these varieties, changes occur not only in the muscles, but also in the ligaments, fasciæ, and in the bones themselves, whether as causes or effects; but we shall defer the study of them until our next meeting, my object in briefly mentioning the primitive deformities now, being merely to impress upon you the character of the changed relation of the parts from an anatomical rather than a pathological standpoint, which latter can be best considered when we come to speak of the most frequent of all the forms of clubfoot, namely, *talipes equino-varus*.

(*To be concluded.*)

ORIGINAL ARTICLES.

TREATMENT OF ACUTE INFANTILE BRONCHITIS.[1]

By J. LEWIS SMITH, M.D.,
CLINICAL PROFESSOR OF DISEASES OF CHILDREN, IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

Infantile bronchitis is probably the most frequent disease which the physician is called upon to treat. It is usually mild and readily controlled by proper remedies, but in other instances, especially when neglected or improperly treated, it becomes by extension downward to the minute bronchial tubes, or to them and the alveoli, one of the most fatal maladies of infancy. It is, therefore, very important that bronchitis in the infant receive timely and proper treatment.

A brief glance at the clinical history of this malady will help to a correct knowledge of its therapeutic requirements. Acute bronchitis is in most instances preceded, and in its first stages accompanied, by coryza, which first arrests the attention of the parents, but within a day or two the inflammation extends to the larger bronchial tubes, and is announced by a cough. The bronchitis is often limited to these tubes throughout the attack, under which circumstances it is so mild that treatment is scarcely required, but between this mild disease and that severe form in which the minute bronchial tubes are involved, there is every grade of severity.

Bronchitis in the infant is primary or secondary. Two diseases are always accompanied by it, in a form so severe that the cough which it causes is a prominent symptom in each, to wit, measles and pertussis. It occurs also in a mild form in typhoid fever, and is present in tuberculosis, and in many cases of diphtheria. It requires, in a measure, different remedies according to the conditions in which it occurs, but the treatment may be most conveniently considered under the two headings of mild and severe bronchitis.

Bronchitis can probably be aborted or rendered milder in some instances by an emetic employed when the first symptoms appear. Its effect is more certain if the patient drink warm water at the same time, and take a warm foot bath or general bath. The syrup of ipecacuanha is perhaps the best medicine for this purpose. It promotes bronchial secretion and diminishes the force of the circulation. But ordinarily the physician is not summoned until the bronchitis is established, and measures designed to abort it are inadequate.

Treatment of mild bronchitis. The inflammation is limited to the larger tubes, or to these and those of medium size; if to the larger tubes, it gives little inconvenience, and often passes off without treatment. The patient is said to have a cold. In mild bronchitis, the respiration is but slightly accelerated, the temperature not above 102°, the cough not painful, or attended by a slight degree of soreness in the upper sternal region; the thirst is moderate, and the appetite not notably diminished.

In this form of bronchitis, in which there is no increase of symptoms from day to day, demulcent and mild expectorant medicines are sufficient to cure the disease. Even domestic remedies are sufficient. It is of such cases that the late Dr. James Jackson, of Boston, in his advice to a young physician, wrote as follows: "For young children I employ the following: Take of either almond or olive oil, of syrup of squills, of any agreeable syrup, and of mucilage of gum-acacia, equal parts, and mix them. Of this mixture, a teaspoonful may be given to a child two years of age, a little less, if younger, and increase if older, so as to double the dose to one in the sixth year."

Of the mixtures officinal in our pharmacopœia, the mistura glycyrrhizæ composita is perhaps the best for mild bronchitis, and it is largely used. It is beneficial not only in the primary disease, but in the secondary or symptomatic bronchitis of measles and pertussis. The small amount of tartrate of antimony and potassium which it contains, $\frac{1}{64}$ grain to the drachm, has a slight sedative effect on the action of the heart without causing nausea, and it promotes expectoration. The paregoric in this mixture being one part to eight, is useful if the infant be restless, and deprived of the needed sleep. A patient of one year can take one-third of a teaspoonful, and one of two years half a teaspoonful, every two to four hours. The syrupus ipecacuanhæ compositus of the French pharmacopœia is also one of the most beneficial remedies for mild bronchitis. It is slightly laxative, and it produces no narcotic effect. It consists of the ipecacuanha and senega roots, thyme, the blossoms of the red poppy, which I believe are not narcotic, orange-flower water, white wine, sugar, and a small amount of sulphate of magnesium. An infant of eight months can take half a teaspoonful every second hour, and one of eighteen months or two years, one teaspoonful every second or third hour. I have prescribed this syrup during the last two years, and mothers who have observed its effects have commended it. As is seen from its composition, it promotes expectoration without any of the ill effects which sometimes result from the use of those mixtures which contain opiates. If it were introduced into our pharmacopœia it would probably be largely used in this country.

If the temperature rise to 102° or above, with the respiration in a corresponding degree accelerated, the cough painful, and the pulse frequent and strong, indicating extension downward of the inflammation, the following prescription I have found useful:

℞.—Spts. ætheris nitrosi,
Syrupi ipecacuanhæ . . āā ℥ij
Ol. ricini . . . . . ℥iij
Syr. bal. tolut. . . . . ℥j.—M.

Sig. Shake bottle and give half a teaspoonful to an infant of one year; one teaspoonful to an infant of two years.

Mild bronchitis, with the use of such remedies as have been mentioned, and with the external treatment of the chest which will be described hereafter, gradually abates in most instances. But the physician should be prepared for the other alternative, namely, an increase in the severity of the symptoms by exten-

[1] Read before the Section of Obstetrics and Diseases of Children, New York Academy of Medicine, January 28, 1886.

sion of the inflammation to the smaller tubes, and the change of a mild into a severe bronchitis.

Severe or grave bronchitis. The inflammation has extended to the minute bronchial tubes: the mucous membrane of these tubes is hyperæmic and swollen, and actively secreting. On account of the small size of the tubes, many of them become occluded by muco-pus, which acts as a ball-valve, allowing the escape of air upward from the alveoli, but preventing its entrance into them. Hence the alveoli connecting with these closed bronchioles become less and less distended with air, undergoing partial collapse, and some of them pass into a state of complete atelectasis. This occurs most frequently in the posterior and depending portions of the lungs.

Another equally serious pulmonary complication often occurs. I refer to catarrhal pneumonia. The inflammation in its progress downward in the most severe forms of the disease, passes from the bronchioles to the adjacent alveoli, usually in more places than one. With the occurrence of this complication, the symptoms are aggravated, the suffering increased, and the prognosis is obviously the more unfavorable the greater the extent of this complication. Bronchopneumonia thus occurring is indeed one of the most dangerous diseases of infancy, and one that requires the utmost vigilance on the part of the physician, and the most skilful use of remedies, to save the life of the patient. The respiration in severe bronchitis is greatly accelerated, numbering 60, 80, or even 100 or more per minute, and each inspiration is usually accompanied by a moan. The pulse is in a corresponding degree accelerated, and is often feeble; the countenance is anxious and indicative of suffering, and the patient restless.

In this form of bronchitis the indications for treatment are: 1. To promote expectoration, and prevent clogging of the tubes; 2. To diminish the inflammation, and prevent its extension; 3. To strengthen the action of the heart and prevent exhaustion.

In employing measures to fulfil the first indication, it should be borne in mind that the cough is useful as the only means of expelling the mucus, and that patients never do well with severe bronchitis that do not cough often. When asked by parents to prescribe something to diminish the cough, I inform them that the safety of the patient depends on the strength and frequency of this symptom, and that it would be dangerous to put a stop to it by the use of opiate or other medicines, and I now very seldom combine an opiate with the cough mixture for severe infantile bronchitis. If the infant be allowed to cough every five or ten minutes, and the cough be rendered as loose as possible by appropriate remedies, it will do better, according to my observations, than when the cough occurs at longer intervals. If it requires sleep, I give medicine separately once or twice daily, as in the following formula for a child of one year:

R.—Liq. opii compositi (Squibb's) . gr. xij.
Potassii bromidi . . . . ℥j.
Syr. rubi idæi (raspberry) . . ℥ss.
Aquæ . . . . . ℥iss.—M.
Sig. Dose, one teaspoonful.

I have seen much harm done by employing stupefying agents which, while they produce sleep, also cause suspension of the cough, upon the strength and frequency of which the safety of the infant depends. The very prevalent opinion among the laity that the cough does no good to the infant unless mucus is ejected from the mouth, needs to be corrected. In order to obtain their full coöperation, I often find it beneficial to explain to the mother or nurse the process of expectoration in the infant, so that they understand that the tubes are freed from mucus as effectually when it is swallowed, after the cough, as when it is received upon the handkerchief.

Among the agents to fulfil the first indication mentioned above—that of promoting expectoration with the least possible loss of strength—the first place must be given to the ammonium salts; of which the two in common use are the carbonate and muriate. The carbonate is both a stimulant and expectorant, but its irritating property is such that it should not be prescribed in a larger dose than one grain to the drachm; a larger dose frequently repeated may produce gastritis, especially if there be little food in the stomach. It has been known to produce gastritis in animals when administered in considerable quantity, and its irritating action on the fauces can be noticed by any one who swallows a solution of two or three grains to the drachm. The Curator of the Foundling Asylum has noticed in the cadaver the ill effects of the more irritating ammonium preparations. In one instance in which the aromatic spirits of ammonia had been employed, it was supposed with sufficient dilution, the extent and severity of the gastritis were such that it seemed as if this agent might have hastened the fatal result. The preferable way of employing this valuable agent, to prevent its irritating action upon the stomach, is to prescribe it dissolved in water, and order each dose to be administered in a tablespoonful of milk. The muriate does not possess the irritating property of the carbonate, and it can be safely administered in double or treble the dose of the latter, and at short intervals. It is therefore, I think, to be preferred to the carbonate in most cases of severe bronchitis, except at an advanced stage, when an active stimulant of the heart is required.

In this connection, I will state my conviction that the ammonium salts, whether the carbonate or muriate, are not given in sufficiently frequent doses in the practice of most physicians, in severe forms of the disease which we are now considering. If there be marked dyspnœa, and urgent need that the mucus be expectorated from the tubes which it is obstructing, I think that the effect is better if the dose be administered every half hour instead of every second or third hour. Half-hourly doses are not inconveniently given if the vehicle be milk.

The muriate of ammonium may, like the carbonate, be administered in milk, but the following is with me a favorite formula:

R.—Ammonii muriat. . . . ℥j.
Syr. bal. tolut. . . . ℥ij.—M.

Fifteen drops, which contain one grain of the muriate, should be given to an infant of three months, and thirty drops, or two grains, to an infant of six

months. Physicians, in my opinion, often defer too long the use of the ammonium salts, using for the first days depressing remedies instead. The infant suffering from dyspnœa, and requiring a strong and frequent cough to expel the mucus, may, according to my observations, take the muriate from the first day of the sickness with benefit; and every half hour or hour when it is awake. No harm can result from the use of this agent in frequent doses, and for several days, such as might result from the carbonate.

The ammonium salts tend to increase the frequency of the cough, perhaps by the slight irritation which they produce upon the fauces in the swallowing. The muriate may be employed so long as an expectorant is required, and usually with as much benefit as can be derived from any drug.

As regards the use of those other common expectorants which have long been employed, particularly senega and squills, those have been better observers than myself who have witnessed any marked benefit from them.

It is so necessary, as a means of relieving the dyspnœa, to assist the infant to expel the mucus with which the tubes are clogged, when the respiration is much embarrassed, that an emetic is sometimes proper. One should be selected which causes little exhaustion. The syrup of ipecacuanha may be employed, given with an alcoholic stimulant, as brandy or whiskey. Infants a few months old I have sometimes temporarily relieved by removing with the finger or a swab the mucus that collected upon the fauces. This simple operation produces a forcible cough, and sometimes vomiting, by which a large amount of mucus is expelled.

The necessity of sustaining the strength of the patient, and, at the same time, of reducing the fever, has led to the employment of quinine by many, perhaps most, physicians in the treatment of severe infantile bronchitis. I cannot say that I have noticed any marked reduction of temperature from its use in bronchitis or broncho-pneumonia, but it has seemed to me that it has been useful as a heart tonic. Much harm may, however, be done by employing quinine in the treatment of infants, by the use of doses too large. In the adult, according to the sphygmographic observations of Dr. M. Putnam Jacobi, while quinia in a dose of five grains increases the strength of the heart's contraction, a dose of twenty grains enfeebles the contractile power of the heart in a marked degree. According to Stillé and Maisch, "Poisonous doses occasion dyspnœa and noisy respiration, which is also jerking, interrupted, retarded, and finally arrested" (*National Dispensatory*). A dose too large, therefore, would be likely to produce just such symptoms as occur in severe broncho-pneumonia. To an infant aged one year, with this disease, I do not give a larger dose than one-half grain to one grain of the sulphate of quinia, every fourth hour, as in the following formula:

℞.—Quiniæ sulphat. . . gr. xij.
Ext. glycyrrhiz. . . ℥ss.
Syr. pruni Virginiani . ℥ij.—Misce.

Quinine, however, administered to an infant is very likely to cause vomiting from its bitterness, a result which I do not regret in the treatment of capillary bronchitis, because it causes the expectoration of considerable mucus. The second or repeated dose is usually not vomited. It is difficult to appreciate the beneficial effects of quinine in this disease, but that it does increase the contractile power of the heart seems probable.

If the temperature rise above 103°, if the infant have a full and strong pulse and flushed face, and if the lungs are not involved, or but slightly inflamed, antipyrin may, according to my experience, be safely administered, in proper dose, and with beneficial effect as regards the febrile movement. It should not be administered at stated intervals, but according to the temperature, so that, perhaps, only one or two doses daily may be sufficient. When the lungs are implicated, and the patient has severe broncho-pneumonia, I have seen such pallor from a single dose of antipyrin, in one instance, that I did not dare to repeat it. It seems to me, therefore, that there should be a careful discrimination in regard to the cases in which it should be employed, so that, while vigorous infants, with severe bronchitis, without pneumonia, or with but slight pneumonia, are benefited by its use, feeble infants, with weak pulse or with extensive pneumonia, and young infants, incur too great risk to justify the employment of this agent, until its exact therapeutic effects are more clearly ascertained.

When the pulse is becoming more rapid and feeble from the extent and severity of the inflammation, the use of digitalis is indicated as a heart tonic. Not infrequently in severe bronchitis, with the minute tubes clogged with muco-pus, the heart is taxed to the utmost to carry on the circulation. Digitalis may furnish the needed assistance by increasing the contractile power of the ventricles. It is, therefore, an important remedy in a large proportion of cases of this form of bronchitis. Two drops of the tincture of digitalis may be given every second hour to an infant of eighteen months, during three or four days, or longer, if the action of the heart be oppressed so as to require it. But no one of the medicines which I have mentioned is more urgently needed in severe infantile bronchitis than alcoholic stimulation. It may be employed at an early stage when the heart begins to fail, without fear of increasing the inflammation. A rule with me is to give two or three drops of brandy or whiskey for each month in the age of the infant after the third month. It should be given hourly, or each second hour, by day and by night, when the infant is awake.

Local treatment. The external treatment of infantile bronchitis has changed greatly within the recollection of the older members of the profession. Thirty five years ago the pernicious teachings of Broussais still had some influence, and the application of one or more leeches to the chest was recommended in the text-books. Leeching did apparently cause some alleviation of the suffering, and, according to my recollection, an easier breathing for a time; but any good which resulted from it was more than counterbalanced by the loss of strength, as indicated by pallor of the countenance and a feebler pulse. It has been properly abandoned during the last twenty-

five years, and is not likely to be employed again as a remedial measure. The same may be said of vesication. Under the teaching of the schools and the books, vesication was employed after the bleeding from the leech bites had ceased. Witnessing the restlessness and increase of suffering which the fly-blister produced, I abandoned its use in the first two or three years of my practice, employing instead the cantharidal collodion, applied in points or small patches, half an inch in diameter, over the anterior part of the chest. It is now many years since I have used the Spanish-fly in any of its forms or witnessed its use in the practice of others in infantile bronchitis, and the disrepute into which it has fallen is not to be regretted.

But how shall the chest be treated? Writers mention the benefit derived from revulsive measures applied to the chest. Prof. Henoch, of Berlin, whose opinions have great weight with all who are familiar with his writings, recommends dry cupping for its revulsive effect. Says he, "Instead of leeches, I now apply wet, and especially dry cups (four to eight, according to the age), as these have at the same time a revulsive effect." The question may be properly asked, Does revulsion do any good? How can producing an afflux of blood to the surface of the chest diminish the severity of the bronchitis, since the bronchial tubes derive their supply of blood from a different branch of the aorta from that which supplies the walls of the chest? However it may be explained, slightly irritating applications which produce moderate redness of the surface of the chest, do seem to assuage in a measure the suffering of the patient, and aid in procuring the needed rest. After observing their effects for many years, I have found no better mode of external treatment for infants under the age of two years, and for all weakly infants whatever their age, than the application of a flaxseed poultice properly prepared. But instruction should be given in the preparation and application of the poultice with all the details which Abernethy was wont to give to his class. A poultice which, in a few hours after its application, lies in a mass upon the epigastrium with the chest bare, does more harm than good. The poultice should be of uniform thickness, of about a line, between two thicknesses of linen, or thin muslin, and so moist that it wets the hands in holding it. For infants under the age of six months, camphorated oil should be thickly smeared on its under surface; for those between the ages of six and eighteen months, instead of the camphorated oil the flaxseed should be mixed with one-twentieth its weight of pulverized mustard, and for those above the age of eighteen months the mustard should be one-sixteenth part. In all those cases in which the respiration is not only hurried, but painful, and accompanied by a moan, and in which the cough is painful, the whole chest should be covered by two poultices, as thin as mentioned above, one over the anterior and the other over the posterior surface, fastened together over the shoulders, and under the arms by small safety-pins, and covered externally by a snugly fitting oil-silk jacket. The poultices thus made should be reapplied morning and evening. They usually cause redness of the surface without pain, but they have never, in my practice, vesicated. They should be continued during the active period of the inflammation. Repeatedly, I have observed the breathing become easier by their use. At the same time, if the febrile movement be so great that it requires to be reduced, an ice bag may be placed upon the head, and the hands and forearms be frequently sponged with cool water or alcohol and water.

Cool water dressing applied to the chest has its advocates, and, although I believe that the poultices give most relief to the majority of infants, it does not seem improbable that robust infants over the age of twenty months with high temperature may sometimes obtain relief from its use. Prof. Henoch writes: "I strongly advise hydropathic applications to the chest from the neck to the umbilicus. A napkin or diaper is dipped in water at the temperature of the room, well wrung out, and then placed around the chest, without exercising any compression, so that the arms are free. This is surrounded by a roll of batting, and then covered by a layer of oil-silk or gutta-percha paper." If the temperature be high, this application should be renewed every half hour, and it may be continued several days. If it be renewed at long intervals, its effect is obviously like that of a poultice.

If the patient begins to convalesce, the application to the chest, whether water or the poultice, can soon be omitted, and batting covered with oil-silk be substituted for it. Finally, the position of the infant, when there is marked dyspnœa, indicating extension downward of the inflammation, should be frequently changed, since a change in position tends to prevent pulmonary congestion, and aid the expectoration. If the infant be placed over the shoulder or upon the lap of the nurse with face downward, its expectoration is often facilitated. Moisture in the room, as that produced by boiling water, also aids the expectoration, probably by rendering the muco-pus thinner and less viscid. When bronchitis occurs in a constitutional disease, as measles or pertussis, as an element of it, it continues as long as that disease lasts, but it can be made milder or less annoying to the patient by remedies such as those mentioned above.

ON THE HEADACHES WHICH ARE ASSOCIATED CLINICALLY WITH CHRONIC NASAL CATARRH.[1]

BY HARRISON ALLEN, M.D.,
PROFESSOR EMERITUS OF PHYSIOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

THE proximity of the nasal chambers to the brain-case would naturally lead the observer to conclude that the relation which exists between the two regions is one possessing exact clinical value; but this is far from being the state of the case. One is inclined to believe that we are sometimes misled by our anatomical knowledge, and stand purblind in the presence of the most evident signs and symptoms which do not happen to harmonize with our previous conception of the

[1] Read by invitation before the Philadelphia Neurological Society, Feb. 22, 1886.

boundaries of regions and of the paths of the blood-vessels and nerves. A frontal catarrhal headache is at once attributed by the physician to the extension of congestion and of inflammation from the nose to the frontal sinus along well-known lines of communication; but should the pain be confined to the temple, to the top of the head or to the occiput, the association with the nose is not so quickly detected, and, indeed, is apt to be ignored. I have been led so often to believe that any disposition to headache which coexisted with catarrh would disappear, or be greatly ameliorated as a result of treatment, that I have ventured to formulate my impressions on the subject.[1]

Description. The headaches of chronic catarrh are of three kinds: the reflex, the neurotic, and the inflammatory.

THE REFLEX HEADACHE.

The reflex headache is almost entirely restricted to the forehead, the temple, and the vertex. In all varieties of chronic catarrh a dull pain in the region of the forehead is complained of, which may or may not be associated with oppression of spirits and with confusion of ideas. When the disease is confined to that plane of the chamber corresponding to the middle turbinated bone the pain is referred to the temple.[2] The patient will often accompany the account of this pain by a gesture. The index-finger is drawn across the face from the middle of the nose to the temple, and thence, in some instances, to the parietal eminence. The track thus begins at the nose and ends at the temple, or a point beyond. It is not a superficial path, but is referred to a locality lying deep within in the face, and is sometimes described as lying back of the eye. The temporal artery is tense and bounding. An attack of pain, which, in a mild form, may be confined to this region of the face and the temple, will extend, in severe attacks, to the vertex, and even to the nape of the neck. In such phases it is often associated with nausea, and is said to be a "sick headache." Less frequently, the pain is referred, in the first place, to the vertex. The slightest exacerbation of the catarrh causes, in some cases, a severe pain at the top of the head with a subjective impression of heat at the spot, and hyperæsthesia of the scalp. In a patient whom I saw recently, through the courtesy of Dr. S. Weir Mitchell, the pain was of a high grade, and from its persistence had thrown the patient into a pronounced state of nervous prostration. In this person a probe touching the right middle turbinated bone—no matter in how slight a degree, or with what considerate care—would be instantly followed by a complaint of vertex pain.

In reflex headache the inner wall of the orbit, when pressed upon by the finger as far as can be accomplished, is found to be peculiarly sensitive. The ethmoidal cells are evidently congested, and the os planum tender. The condition of the nasal mucous membrane is one of intense inflammation, which has involved the submucous connective tissue, if not the bone itself. The parts are often in an atrophic state.

In one case the complaint of general cephalalgia and *clavus* over the right parietal eminence was noted. The nasal disease was confined to the middle turbinated bone of the corresponding side, and was associated with excessive sensibility of the parts. Moderate but persistent bleeding occurred from an ulcer on the corresponding side of the septum.

A lady who had been for years suffering from recurrent headaches found not only that the attacks came most frequently when she was suffering from exacerbations of the nasal distress, but that they might also ensue upon emotional excitement, overwork, or upon prolonged or too free menstruation.

Diagnosis. The headache of catarrh, while not fully described in any treatise which has come under my notice, has been mentioned by J. Macculoch.[1] According to this writer, "Periodical catarrh sometimes so predominates over the headache as to appear the sole disease; not unfrequently also being of a severe and durable character, ... also, by what is called sympathy, often affecting the other nostril, and thus entirely deceiving both patient and practitioner into the belief that it is an ordinary catarrh. Such an affection often teases a patient through months or even years, as do all these diseases; and I have little doubt that many of the habitual catarrhs do belong to this hemicrania."

In the "hemicrania" thus referred to, the "pained part is generally small"—and restricted to a point over the brow or to the top of the head. The spot is so small as to be covered by the tip of the finger. We have here a form of *clavus* of malarial disease, which can be distinguished from *clavus* of ordinary catarrh, by its periodicity and by the history of malarial exposure.

From the headaches of cerebral disease the headaches of catarrh are sharply separated. The absence of any symptom referrible to cranial sources, the lack of evidence furnished by the history of the case that the complaint is of central origin, the complete control of the condition by local treatment, easily distinguish the affection last named.

Reflex catarrhal headache can be distinguished from "sick headache" of gastric origin by the absence of gastric disturbance, such as the furred tongue, from the temporal pains of eye-strain, by its persistence after the correction of the errors of refraction, and, with less exactness, from neuralgia of the head by exclusion of the rather multiform causes which are found to constitute this condition. Of necessity, it is possible to have a neuralgia of the variety last named or a condition following ciliary strain, as well as dyspepsia, in the same group of symptoms. With a single exception, it has so happened that I have never met with cases in which such associations existed.

[1] In THE MEDICAL NEWS of January 30th an interesting discussion appeared on "Reflex Symptoms in Nasal Affections," as reported from the Proceedings of the New York Academy of Medicine. The paper herewith presented was written before the discussion referred to took place. It is noteworthy that the general character of the affections described has received at the hands of observers working independently of one another essentially the same elucidation.

[2] A probe passed in the nose, so as to enter the space defined between the inferior turbinated bone and the outer wall of the nose, often excites a sensation which is referred to the region of the lachrymal sac.

[1] Marsh Fever and Neuralgia. London, 1828. ii, 39, 44

The diagnosis of catarrhal headache can be made by noticing the effects of pressure upon the inner wall of the orbit. If it be observed that the characteristic pain ensues when this surface is thus disturbed it is a proof that the pains are not induced by causes *extra limital* to the nose.

The headaches of lithæmia can be distinguished from those of catarrh not only by the tests for uric acid deposit, but, as a rule, by the general appearance of the patient. The sufferer from any of the forms of chronic nasal catarrh never enjoys average good health and does not present the robust aspect of many subjects of lithæmia.

It has been seen that when the headache is persistent it may become a cause of nervous prostration. This event is the more likely to occur in those patients who, from a variety of reasons, are already debilitated and in those who are especially susceptible to the depressing effects of pain. Such phases of the general subject have the same clinical value as tinnitus aurium or illusion in disturbing the mental balance. A person predisposed to hysteria, to hypochondriasis, or to melancholy, will find in the headache an excuse for the general complaint. Oftentimes the nasal disease offers the single local obstacle to successful treatment.

In one case the headache was coincident with a true neuralgia. The patient distinguished between the affections by the catarrhal headache being constant while the neuralgia was intermittent. The former proved to be the more amenable to treatment.

The application of solutions of the hydrochlorate of cocaine is often followed by headache and insomnia. This condition, which may receive the name of the *cocaine headache*, can be detected by the absence of exact reference of the pain to limited regions of the head and by the fact that the pain is always a sequel of the use of the drug.

The rheumatic headache differs from the catarrhal in the absence of the temporal throbbing, and of the elevation of the temperature of the scalp. The pain of rheumatism ordinarily involves the temporal and the masseter muscles.

Megrim is apt to induce injection of the conjunctival vessels, and to excite subjective visual phenomena. It is besides periodical, and the hereditary character of the affection is more pronounced than in the headache of catarrhal origin.

The so called "nervous headaches" as distinguished from the headache of neurotic subjects (*q. v.*), are associated with general prostration, and are commonly coincident with the menopause.

Perhaps the best evidence of the limitation of catarrhal headache is determined by what Marshall Hall has called the therapeutic aid to diagnosis. The catarrhal headache disappears when the nasal catarrh is cured.

Etiology. Cases of catarrhal headaches which are reflex in nature, are far more numerous than either the neurotic or inflammatory.

Unless the cribriform plate and the upper portions of the lateral masses of the ethmoid bone be seriously involved, either by malignant growths or by necrosis, the meninges of the brain do not suffer in any of the affections to which the nasal chambers are subject. Even the traumatic causes of meningeal inflammation, which may be referred to the nose, are very rarely met with in private practice. It may be broadly asserted that the headaches of nasal disease are not of meningeal origin, but, as a rule, are reflex in nature. A great number of the paths of clinical reflex symptoms are conjectural, and it would be a fruitless task to endeavor to set down, with any show of accuracy, the directions taken by the afferent and efferent nerves in producing from a peripheral irritation within the nose a painful sensation in the head. Catarrhal headache is best considered, therefore, entirely from the clinical standpoint. It is a curious circumstance that the reference of a transient pain to the teeth, or to the roof of the mouth, as well as the occurrence of suffusion of the conjunctiva and the flow of tears, which so commonly ensue upon surgical interferences in the nasal chambers, do not often find a place among the conditions complained of in the study of catarrhal headaches, excepting in the neurotic form of the so-called "hay fever." I have sometimes been induced to believe that the headaches might be vaso-motor reflexes, and be confined to the great meningeal artery and its branches, but this position cannot be maintained.[1]

Special stress must be laid upon the compression of the anterior end of the middle turbinated bone. If the pain is referred especially to the side of the nose at about the level of the tip of this bone, and extends from this point to the various parts of the head which have been enumerated above, it may be said to be due to the squeezing of the tip between the walls of the nose. The vertex pain is frequently associated with pressure of the entire bone against the septum. Such extensive compression impairs the vitality of the septum, and an acquired ulceration of the septum (if not actual perforation) is apt to occur at the middle of the triangular cartilage.

While it must not be supposed that disease of the middle turbinated bone, of necessity, creates a reflex pain in the head, yet the existence of such a pain aids the observer in locating the lesion. All things remaining the same, the presence of a broad middle turbinated bone, the covering membrane of which is in a state of chronic inflammation, and which is tightly wedged between the lateral and the median walls of the nasal chamber, will predispose the subject to attacks of cranial pain.

[1] Reflex headache may have its origin in the pharynx. At least the symptoms disappear upon the relief of the pharyngeal distress. As is well known, pharyngeal disease is often a sequel of nasal disease, and the congested state, which creates the sensation of fulness and pain in the pharynx, may also cause the pain which is referred to the head. A striking example of this complaint was observed by me in the person of a lady, the wife of an army officer, who had spent several years in the high, dry altitudes of the Rocky Mountain range. When first seen, she had just recovered from an attack of neuralgia of the spine. The pharynx was the seat of deep-seated infiltrations which were accompanied by a sense of fulness and of a choking sensation. Conversation was sustained with effort, while reading aloud was painful, and in a short time impossible. After the pharyngeal symptoms subsided a disposition to attacks of "sick headaches," which she had had for many years, to the surprise of the patient, disappeared. No complaint at any time had been made of the nose, and certainly no evidence of disease in the nasal chambers was apparent.

THE NEUROTIC HEADACHE.

By the neurotic headache, when seen in connection with catarrh, may be understood that state of the system in which a very moderate extent of local nasal or pharyngeal disease excites numerous and inconstant symptoms which cluster about the region of the head and throat. In a typical instance of the kind, the patient—a highly neurotic person—complained of a pain in the throat and ears, in the head, and back of the throat, of a dryness in the roof of the mouth and the nostrils, and of a parched feeling in the eyelids. At another time these inexact symptoms were supplanted by a sensation which was described as "drying the head up." It is evident enough that these complaints cannot be said to constitute a true headache. And yet it is of practical value to remember that the patient was greatly improved by a course of local treatment to the nasal and pharyngeal mucous membrane, at the same time due regard was given to the removal of the causes which had induced the prostration of the nervous system.

It is at first sight a fact suggestive of the neurotic basis for the entire group of catarrhal headaches, that the subjects, for the most part, are females. I have notes on three cases only of headache occurring in the persons of overworked merchants. One of these gentlemen was, at the time he came under my observation, a sufferer from an advanced form of pyrrhorrhœa alveolaris. He was, also, a subject of headache of a grave form. It was not a temporal variety of the complaint, and did not appear to be aggravated by the moderate amount of nasal disease which was coincident with the state of the gums.

I have not hesitated to include the majority of the cases under other heads, and to reserve for the neurotic variety those cases which exhibited an amount of local disease which, in my judgment, was not sufficient to account for the symptoms. Perhaps a safe predicate to explain the facts is to be found in the relatively larger number of instances of chronic nasal catarrh, which come under notice in private practice, in females than in males.

HEADACHES OF INFLAMMATORY ORIGIN.

Catarrhal headaches of inflammatory origin I have never seen, except in acute congestion or inflammation of the frontal sinus. The pain is of high grade, and is, as a rule, confined to one side. In the cases I have studied there has been no elevation of the temperature of the body, and the attacks have subsided after the application of leeches.

Under the heads of *prognosis* and *treatment* little is required to be said. It is evident that if the premises assumed above be correct, that the catarrhal form of headache will continue until the local cause is removed.

All things remaining the same, the patient can be assured that the distress can be relieved by a system of local treatment. The relief is quickly attained when the diseased structures are limited to small patches of the nasal mucous membrane, but is, on the other hand, when the surfaces are extensive, reached only at the end of a long and tedious course of local treatment. I recall, in this connection, a case of a young lady, who came under my care against the advice of others who thought that, as a result of the serious impairment of the general health, the rest treatment should precede the ordeal of cautery treatment to the nose, yet who advanced steadily in improvement under the treatment, in spite of a headache of the gravest type.

The treatment is in no way modified from that which I have advocated for the treatment of chronic nasal catarrh. The diseased structures must be removed as thoroughly and as rapidly as is consistent with all the facts, and in obedience to the general principles and practice of surgery. In two cases marked relief followed the retention of obturators of vulcanite in the spaces left by perforating ulcers of the septum.

In conclusion, it may be said that, while the headaches of catarrh are not absolutely outlined from the numerous forms of cranial distress into which the brow, the temple, the vertex, and the occiput may be involved, it is worthy of a position as distinct, and of a grade as important, as that allowed the headaches of eye-strain, or even of megrim itself.

A NOTE ON LEWININ, THE NEW LOCAL ANÆSTHETIC.

By N. A. RANDOLPH, M.D.,
INSTRUCTOR OF PHYSIOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

In the editorial columns of The Medical News of February 13, 1886, there is given a brief account of the physiological properties of a semifluid resin obtained from the root of *Piper methysticum*.

In the method employed in obtaining it (extraction by petroleum-ether) two resinous bodies are obtained, the resin of lesser density only being efficient. To this body Lewin, its discoverer, applies in his original communication the rather cumbrous title of "Alpha Kawa Resin," for which I have ventured to substitute the name lewinin, as above.

Although I have not been able to obtain, in my experiments with the extract in question, results as marked as those presented by Lewin, several points of clinical interest have arisen, which will, I think, be of interest.

When the semifluid lewinin is placed upon the tongue, there is a momentary burning sensation with increased salivary secretion, followed by a local numbness, which, while extremely superficial, is recognizable for more than an hour. Some pallor of the mucous membrane at the point of application is noticeable. I have several times swallowed about five grains of the extract thus placed upon my tongue without appreciable results other than those noted.

Lewinin is too painfully irritating to apply in practice to the human conjunctiva, but it is my belief that, by the previous application of cocaine, the lewinin in solution could be instilled into the conjunctival sac, and produce its characteristic effect of prolonged local anæsthesia before the more temporary effect of the former drug had passed off.

The extract will probably be of service in dental

practice, as its application certainly mitigates the discomfort of operations on the teeth of those suffering from sensitive dentine.

The most marked practical benefit, however, to be expected from the use of the drug is in cases where only a relatively superficial anæsthesia is desirable. Thus, as would have been expected, the drug is of value in rhinological practice.

Dr. Harrison Allen, to whom I handed a fifty per cent. alcoholic solution of lewinin, kindly reports that, in practice, he has found a number of cases of nasal trouble in which the drug could not only be availably substituted for cocaine, but in which its action was more satisfactory.

The extract just discussed was prepared for me something over a month ago by Mr. Llewellyn, of this city, and was, I believe, the first specimen of the drug produced in this country.

MEDICAL PROGRESS.

Retraction of the Penis.—In the *Vratch*, No. 26, 1885, p. 423, Dr. A. A. Ivanoff, of Büzülük, Samara Government, publishes the following singular case. A strongly built, generally healthy, married peasant, aged twenty-three years, came to a local hospital, evidently laboring under some mental trouble, and stated that "something had broken down below" with him. On stripping the patient a string came to light, one end of which encircled the retroglandular sulcus of the penis, while another end was fastened round the lower part of the left thigh, the member being thus kept down in a tightly stretched case. The patient did not allow the author to touch the arrangement, and himself untied the femoral end of the string. On gradual relaxation of the latter, the penis slowly retracted, and ultimately disappeared altogether under the pubic arch, leaving only a navel-like depression. The part could be got back only by traction on the string. According to the patient's narrative, everything had been in due order up to five days previously, when, having got up to micturate in a dark night, he was utterly frightened at being unable to feel any trace of his penis. Having managed somehow to pass urine, he, after prolonged manipulations, at last succeeded in getting it back, and secured it in the way mentioned. Except slight perineal pain, no other symptoms, and no possible cause whatever for the retraction could be detected. To allay the pain and the patient's distress, bromide of potassium, in ten grain doses every three hours, was given. On the next day the penis remained unretracted for an hour or more. Six days later, retraction disappeared, and did not return. Dr. Ivanoff has not been able to find another similar instance recorded in medical literature.—*London Medical Record*, February 15, 1886.

Treatment of Vascular Tumors.—Dr. Floriani has successfully employed the following mixture in six cases of telangiectatic tumors:

Mercuric bichloride	3 parts.
Collodion	20 "

The liquid is applied with a fine brush to the seat of the tumor, four coats being thus superimposed, and care being taken that each is thoroughly dry before the next is applied. A crust is shed in four days and the fluid again applied as before, until the tumor has disappeared. This treatment is described as absolutely painless; and the resultant pink coloration soon disappears. It is applicable only to flat swellings—*i. e.*, those not much more than a line in thickness.—*Gaz. Hebd. de Montpellier*, Feb. 6, 1886.

A New Mode of Administering the Phosphates.—Dr. Cano Quintanilla writes in *El Dictanem* that the phosphates, which theoretically ought to give good results, do not always do so, because of their insolubility. He says that this difficulty can be overcome by making use of cows or goats. He gives two ounces a day of phosphate of lime, mixed in the feed, to a cow, or five drachms to a goat In a few days the animal's milk becomes much thicker, and is found to contain a large amount of phosphate of lime in a soluble state. This milk may then be given to patients when the phosphates are indicated. The author has employed this method with success in rachitis.—*New York Medical Record*, February 20, 1886.

Experimental Production of Aortic Insufficiency.—François Franck has studied the immediate and remote effects of artificial lesions of the semilunar valves, produced in a large number of animals by means of special instruments introduced into the right carotid. In those animals which survived the operation, the arterial tension, which at first fell, rose again; compensatory hypertrophy ensued and vascular activity increased. According to Franck, the excessive cardiac action was due, not to the aortic regurgitation, but to the irritation of the region of the semilunar valves, inasmuch as very slight lesions or even superficial excitation of this region produces the same results. The gravity of the syncope observed—aortic insufficiency—is ascribed to the prolonged distention of the heart and to the depression of the encephalic circulation.—*Gaz. Hebd. de Montpellier*, Feb. 13, 1886.

On the Poisonous Substances Extracted from Edible Mushrooms.—Roux and Houdé have been able to extract from mushrooms, after putrefaction, several poisonous bodies of an alkaloidal nature, to which they give the name *cryptomaïnes*. Both of them partook of the mushrooms, when freshly gathered, employed in their experiments without any ill effects. The chemical process used for the separation of these bodies is not described. The length of putrefaction has a great influence upon the quantity of these substances that can be obtained. Thus the greatest yield is obtained after the mushrooms have putrified for three or four days, whilst at the end of two months not a trace of a poisonous alkaloid remains.

The *cryptomaïnes* are either liquid or amorphous substances of a slightly dark color, of a bitter taste, and have a very strong odor, resembling that of the plug of a tobacco pipe. Their reaction is strongly alkaline, and with acids they yield salts not easily crystallizable. The mixed substance obtained can be divided into three, a part soluble in ether, another in chloroform, and a third in amylic alcohol. They yield a white pre-

cipitate, with a solution of iodine in potassium iodide, and a maroon crystalline precipitate with platinum tetrachloride reactions given by the alkaloids. Ptomaines, substances obtained by the putrefaction of animal substances, are said to differ from the ordinary alkaloids, with the exception of morphine and atropine, by reducing potassium ferricyanide to potassium ferrocyanide, which then gives a precipitate of Prussian blue with ferric chloride. Cryptomaines exhibit the same reaction. A dose varying from two to twelve centigrammes (0.3–1.8 grs.) of four products was administered subcutaneously to four guinea-pigs, with a uniformly fatal result after a variable time which never exceeded seventeen hours. The portion soluble in ether produced no symptoms until four hours afterward, when the gait became tottering, and the animal did not make any signs of sensation when pinched; death resulted five hours after the injection. The portion soluble in chloroform produced convulsive seizures, short and jerky respirations, paralysis of the hind limbs, and finally death five hours afterward. The amylic alcohol portion caused death in fifteen hours, without any special symptoms. The resinous matters caused feeble rapid respiration, and death in fifteen hours.—*Manchester Medical Chronicle*, February, 1886.

Ptomaine of Stale Fish.—Last year several cases of poisoning by stale sturgeon occurred at Kharkov; five terminated fatally. Anrep, studying the cause of these accidents, showed that a ptomaine was the efficient cause, and could be extracted from the fish, as well as from the contents of the stomach and intestines, the liver, blood, brain, and urine of the victims (*Revue des Sciences Médicales*, No. 53, p. 66). The alkaloid differs from the ptomaines of Brieger. It is an amorphous, highly alkaline body, forming soluble salts, and extremely toxic. Caustic agents and boiling destroy the toxic power of the alkaloid, which has two chief characters—viz., its fixity whether in the solid state or in ethereal solution, and the slowness of its reducing action on the blood. The hypodermatic injection of a quarter of a milligramme in a dog causes vomiting, mydriasis, general prostration, and slowness of the movements of the heart. In the rabbit the action is much more rapid, and the above-mentioned dose causes death in two hours. The march of the symptoms in the poisoned individual is in harmony with the results of physiological research, and indicates, according to Anrep, that the poison first paralyzes the spinal cord, then the medulla oblongata, and acts probably also upon plain muscular tissue.—*Lancet*, Feb. 20, 1886.

Prophylaxis of Gonorrhœa.—Haussmann, following up the undoubted favorable results of prophylactic instillations for the prevention of blenorrhœa of the conjunctiva in the newborn, advises the injection of a two per cent. solution of nitrate of silver into the urethra after a presumably unclean cohabitation. Ten drops of the solution suffice to destroy the gonococci; the injection should be made, however, within a quarter of an hour after exposure.—*St. Louis Medical Review*, Feb. 27, 1886.

Changes in the Cardiac Ganglia in Infectious Pneumonia.—Vinogradoff, in a communication made before the First Russian Medical Congress, states that in infectious pneumonia certain changes are to be noted in the intracardiac ganglia situated on the hinder surface of the heart and between the ventricles. The nuclei disappear, and the ganglia themselves become cloudy, swollen, and granular. The change noted in the ganglia is usually out of proportion to that observed in the heart muscle.—*Wiener Medizinische Presse*, Feb. 7, 1886.

Milk-diet in Chronic Nephritis.—In view of the fact that milk-diet had been emphatically recommended by many observers (Senator, Sparks, and Bruce, etc.), Dr. A. S. Trubatcheff (*Vratch*, No. 46, 1885, p. 763) undertook a series of comparative observations on four patients with chronic nephritis (three with the parenchymatous, one with the interstitial form), each of whom received ordinary hospital diet during one period, and either mixed or pure milk-diet during a subsequent period of equal duration. The results were as follows: 1. An exclusive milk-diet invariably led to a marked increase of the daily and percentage amount of albumen in the urine. 2. The patient's weight fell considerably, without any marked change in his dropsical state. 3. A mixed milk-diet also led, in the majority of the cases, to an increase in the daily and percentage amount of albumen excreted. 4. Neither pure nor mixed milk-diet produced any marked increase in the amount of urine. The author is now studying the assimilation of protein by nephritic patients receiving milk-diet, which study will enable him to settle the question of "good or harm" of the treatment.—*London Medical Record*, February 15, 1886.

Primitive Endocarditis in Soldiers.—In a paper thus entitled, Fournier presents the following conclusions:

1. Primitive endocarditis, a very rare affection in the ordinary conditions of life, tends to become frequent in the military profession.

2. It is developed in this class under the influence of cold or of the fatigue of long marches.

3. It should be immediately opposed by energetic treatment in order to obviate the formation of fibrinous deposits.

4. The most advisable treatment consists in the application of wet cups to the cardiac region, followed by flying blisters. This treatment is followed by a very rapid amelioration of the condition.—*Revue Médicale*, Feb. 13, 1886.

Effervescent Enemata in Intestinal Obstruction.—Dr. J. A. Vondrodsky, of Irkutsk, details a case (*Proceedings of the Eastern Siberian* [*Irkutsk*] *Medical Society*, 1885, p. 100) of intestinal obstruction of five days' duration, where, after complete failure of purgatives and large enemata, the author resorted to effervescent injections repeated at intervals of several hours. After a few enemata, the patient passed a liquid stool, tympanites and fecal vomiting ceased, and complete recovery followed. The enemata consisted as usual of two injections successively administered, one of them being made of a solution of three teaspoonfuls of tartaric acid in a glassful of water, and another of a solution of four teaspoonfuls of bicarbonate of soda in the same quantity of fluid.—*London Medical Record*, January 15, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, MARCH 13, 1886.

OPERATION FOR TUMORS IN THE BLADDER.

In The Medical News of August 25, 1885, we called attention to the statistics of Dr. Stein, of New York, published in March of that year, in regard to operation for the removal of tumors in the bladder. Since that time a number of contributions to the literature of the subject have appeared to bear witness to the attention it has attracted. From some of them we draw the materials for further remarks upon it. It need hardly be said that it is the almost unanimous opinion of surgeons, that tumors of the bladder are comparatively easy of diagnosis, and that operative interference for their removal, or for the amelioration of the distressing symptoms to which they give rise, is in most cases proper.

Since the appearance of the paper of Bazy (*Annales des maladies des organs génito-urinaires*, Oct. 1883), the most important studies of the subject have been the thesis of Pousson, "De l'intervention chirurgicale dans le traitement et le diagnostic des tumeurs de la vessie dans les deux sexes" (Paris, 1884), and the lectures of Sir Henry Thompson, "On Tumors of the Bladder," now published in book form. Of the latter it is not necessary to say much, as the author's views are so well known; although we may remark that his recent conversion to the suprapubic operation of lithotomy may be expected to lead him to a better opinion of the plan of removing tumors by the same method than he expressed in his lectures. The thesis of Pousson discusses the subject indicated in its title with great thoroughness, and his conclusions—which may be said to be those now most generally held—may be epitomized as follows: Benign neoplasms in the bladder are more common than malignant growths. Both are oftenest situated at the base of the bladder. Both are apt to be pedunculated. Ganglionic and general involvement are rare. Inflammatory lesions of the bladder are a late manifestation, and are exceptional; the same is true in regard to the kidneys. The diagnosis rests upon rational and physical signs, of which the former are usually the more helpful. When palpation through the abdominal wall, or through the wall of the rectum, discloses the presence of a tumor, it is more apt to implicate the walls of the bladder and to be difficult of removal; when it does not, the new growth is more apt to be limited to the mucosa and to be easy to remove. Pousson rejects the *boutonière* as a method of diagnosis.

As to operating, he holds that it is permissible when the diagnosis is certain, and when the tumor is small and pedunculated and not causing any great trouble; it is obligatory when the tumor is pedunculated, sessile, or unpalpable, whenever grave accidents occur, such as pain, hemorrhage, frequent micturition, or retention of urine; it is contraindicated in very early life, when the neoplasm has become generalized or widely extended, when the bladder is extensively adherent to the surrounding parts, or when there is serious disease of the kidneys. On the other hand, severe cystitis or hemorrhage does not contraindicate the operation. Indeed, the bladder may be opened when hemorrhage is actively going on, with the expectation that this will make it easy to control the hemorrhage.

As to the method of operating, Pousson advocates dilating the urethra in females, and performing suprapubic cystotomy in males. These opinions rest upon a careful study of the details of fifty-eight cases, reported in the twelve years preceding the preparation of his thesis.

Admitting the general correctness of Pousson's conclusions, it may be said that his strong preference for the suprapubic operation indicates the ardor for the method which now characterizes the French surgeons, and which stands in marked contrast to the rejection of it which was so universal ten or twelve years ago. The English have not yet come to prefer this method to the perineal operation, with which the names of Mr. Whitehead and Sir Henry Thompson are so inseparably connected; and American surgeons, with a few exceptions, may be said to reflect the opinion of the latter. On the continent, too, the perineal operation is not without supporters. Dr. Riedel, in a paper entitled "Zur Operativen Behandlung der Blasenpapillome," published in the *St. Petersburger med. Wochenschrift*, of May 18, 1885, says that, while the suprapubic operation gives a better opportunity to recognize the exact size and relation of a tumor in the bladder, the perineal operation is safer.

Wittelshofer, in a paper entitled "Die Tumoren

der Harnblase," in the *Wiener med. Wochenschrift*, Nos. 34, 35 and 36, 1885, says that a perineal incision helps in the performance of a suprapubic operation, and advises an exploration through the former as a first step, and having recourse to the suprapubic operation only when removal by the perineal route seems unadvisable.

Even in France, Sabbatier, in a paper entitled "Revue critique sur 47 cas de tumeurs de la vessie, etc.," in the *Revue de Chirurgie*, July and August, 1885, recommends operating by the perineal route for benign, small, and solitary tumors situated on the trigonum vesicæ, and reserves the suprapubic operation for malignant, large, multiple, and diffuse tumors, and for those situated on the upper hemisphere of the bladder. Dr. Bazy, in the paper before referred to, expresses a preference for the suprapubic operation.

From this it will be seen that the suprapubic operation may be said to occupy a position which is similar to that called "advanced" in political affairs, while the perineal operation is supported by those who may be compared to the "conservatives." It is too soon for a final judicial opinion as to the superiority of either of these methods. Doubtless there is much to be said in favor of each. But, for the present, the bolder surgeon may feel justified in choosing the former, while the more cautious will with propriety adhere to a method which seems to have less risk connected with it, even if it does not offer so much in the way of precision and completeness in operating.

SYDENHAM ON HYSTERIA.

The words hysteria and hysterical are becoming less frequent in medical writings. Many now use the terms neurasthenia and neurasthenic as substitutes, and, indeed, they are often synonyms. The word hysterical applied to their disorder would be regarded by some patients as a disgrace if not an insult, and all respect for, and confidence in their medical attendant would be lost, while if he tells them they have neurasthenia their minds rest in sweet peace, for this can be no vulgar disease; the term seems both learned and euphemistic.

There is, too, another advantage in replacing hysteria by neurasthenia, for the former carries in its etymology a falsehood, while the latter expresses a truth, and is in some good degree a just guide to the necessary therapeutics.

And yet is there not in the multiplication of medical terms, or in the application of words, danger of complicating our science and confusing the practitioner? Must we magnify simple associated phenomena attending a disorder into disease? For example, even if we must have neurasthenia and neurasthenic, why should spinal irritation be given a place in the catalogue of diseases? It is usually one of the many manifestations of hysteria, and hence, if looked upon as a disease of itself, the other phenomena of the disorder may escape proper attention; and, on the other hand, if it is neglected, and those only treated, the cure also fails. Divide and conquer may be an appropriate maxim in the acquisition of medical knowledge; but in binding up the separate facts thus acquired, in reducing them to order, in forming them into systems, and in the deduction of general laws, we may multiply too much, make arbitrary distinctions, like the multiplication of petty European principalities of a few square miles, with purely arbitrary or conventional boundaries. However this may be, we turn back for a moment from the medical science of to-day, rich in observations, in discussions, and in verbal contributions, to the simple description of hysteria given more than two hundred years ago by one of the wisest, most careful, and conscientious of English physicians, Thomas Sydenham.

In considering the causes of the disorder, Sydenham gave great and deserved importance to debility, and to powerful mental impressions; he utterly rejected its uterine origin, a notion which had been held for centuries and of which its name is significant, but sought this in "a confusion of spirits," too many of them "collected in a crowd" in one part, and, therefore, that part and also the part from which they have been withdrawn suffer. How graphically in the following passages he describes the multiform manifestations of hysteria! "A day would scarce suffice to reckon up all the symptoms belonging to hysterical diseases, so various are they and so contrary to one another, that Proteus had no more shapes, nor the chameleon so great a variety of colors. And I think Democritus was pretty right (tho' he mistook the cause of the disease) when he wrote in an epistle to Hippocrates, that the womb was the cause of six hundred miseries, and of innumerable calamities. Nor are they only very various, but also irregular, that they cannot be contained under any uniform type, which is usual in other diseases, for they are, as it were, a disorderly heap of phenomena, so that it is very hard to write the history of the disease."

The greater frequency of "hysteric disorders" in women than in men, he explains by saying that "kind nature has bestowed on the former a more delicate and fine habit of body, having designed them for an easy life, and to perform the tender offices of love."

Sydenham describes the frequent manifestation of the disorder, as the so called "mother fits," the copious and rapid secretion of urine, "clear as rock-water," the backache, the pain in the head, especially the *clavus hystericus*, hysterical vomiting, retention of urine, salivation, fits of weeping, etc.

In referring to fits of weeping, he states that men are rarely subject to them, but then describes the case of a gentleman who had an attack of fever, to whom he was first called when he was convalescent; the patient had been bled, purged three times, and forbidden the use of flesh. Sydenham states that sitting down and conversing with him, "I presently took notice that his lower lip was thrust out, and moved frequently, as froward children used to do when they prepared for crying, and then wept so violently that I scarce ever saw the like, and with such deep sighs as were almost convulsive." The cure was effected by the moderate use of animal food and of wine.

Unfortunately his first treatment of all cases was not so wise. Misled by his theory that "the ataxy of the spirits has vitiated the humors," he held it "fit first to lessen these humors so corrupted, by bleeding and purging, if the patient has sufficient strength;" but he very frankly states that these patients are thus for the time made worse. After the bleeding and purging, or immediately in patients too weak to bear this treatment, chalybeates and vegetable tonics were given. He states the following very interesting fact, which may have been the germ of recent treatment of neurasthenic disorders by milk: "Some, however, that have been troubled a long while with hysterick diseases, and even such as have frustrated all the endeavors of physicians, yet have recovered by dieting themselves for some time only with milk."

INTRAPARENCHYMATOUS INJECTIONS IN PHTHISIS.

The value of intrapulmonary injections in phthisis has not yet been determined. Although satisfactory results have been reported by Pepper and others, the method has not come into general use. Various substances have been employed, such as iodoform, carbolic acid, and iodine, and now Gouguenheim reports, in *Gazette Hebdomadaire*, No. 3, 1886, the results obtained in 33 cases with solutions of corrosive sublimate varying in strength from 1 : 500 to 1 : 2000. The injection was made with an ordinary Pravaz syringe, the contents of which were thrown directly into the affected portion, or into the cavity. No unfavorable symptoms followed in any case, and, as a rule, the injections were painless. The chief improvement noticeable was in the local signs, diminution of the râles, and lessening of the expectoration, but the general condition was not benefited. Twenty-one cases showed these favorable results, ten died, and two discontinued the treatment. In three of the fatal cases there were indications in the lungs that the injections had done good.

In the discussion which followed the reading of the paper at the Société Médicale des Hôpitaux, Dieulafoy stated, as the outcome of his observations, that he had never noticed any local or general improvement follow intraparenchymatous injections, and in the fatal cases he had not seen changes in the lesions which could be attributed to the beneficial effects of the remedy.

There are two conditions in phthisis in which this mode of medication may prove serviceable. In the early stage, when the disease is localized at an apex, and the tubercles are beginning to soften, repeated injections of the sublimate solution may check the advance of the process, and promote the indurative changes essential to a cure. Secondly, in the advanced stage, when there are large cavities which require disinfection, this mode of treatment is most rational, and will doubtless be more generally employed than it has been heretofore. The purification of the stinking contents of some cavities by inhalations is a hopeless procedure, and in such cases the injections will be found to answer the purpose.

THE PANACEA OF MODERN GYNECOLOGY.

Winckel, in his *Lehrbuch der Frauenkrankheiten*, which has just been published, speaks of laparotomy as the panacea of modern gynecology. Such conservatism is not in correspondence with the spirit of the times when so many speak of a "Battey," or of a "Tait," as a frequent event, and regard extirpation of the ovaries, or of the tubes, or of both, as an operation the indications for which are often presented and are unequivocal. Possibly, however, the voice of conservatism ought to be heard in this, as well as in some other departments of operative gynecology. If the history of some at least of those whose sound ovaries have been removed were given months, or a year or two after the extraction, it would be found that no good had resulted. Winckel regards the time as not far distant when the extirpation of the healthy ovaries for the cure of dysmenorrhœa, ovaralgia, epilepsy, hysteria, and mental disorders will be considered in the same light as clitoridectomy, except that the latter was much more innocent and harmless.

PERSONAL NOMENCLATURE IN MEDICINE.

The application of the names of individuals to discoveries, to instruments, or to operations is liable to cause confusion in knowledge, and in some cases injustice. Names of objects ought to be, so far as possible, descriptive, and not for personal glorification, or for the perpetuation of an individual's name.

We are more than ever impressed with this truth from reading a recent paper by Doléris upon shortening the round ligaments, an operation which is generally known as Alexander's. In the paper referred to, the author very clearly proves that the operation in question was first suggested in 1840 by Alquié, that Aran in his treatise on diseases of

women, 1858, spoke of Professor Alquié's proposed operation as one which if not impracticable, at least presents serious dangers and difficulties, and stated that it was first done by a Belgian surgeon, Dr. Deneffe, twenty years ago; Deneffe's attempt failed.

Doléris quotes from Zeiss's article in the *Centralblatt für Gynäkologie*, the following remarks in reference to the matter: "When one wishes to apply to medicine the methods employed in zoölogy, that is to say, giving new animals the name of their discoverers, one ought at least to choose the name of him to whom really, by just, uncontested right, belongs the merit of the discovery. What a delightful future for the struggle for priority!"

In some few instances the vanity or the quackery of the inventor or the discoverer, but in more the admiration or the sycophancy of others, furnishes the explanation of the personal nomenclature which is becoming so common in medicine.

REVIEWS.

The Technology of Bacteria Investigation. By Charles S. Dolley, M.D. 12mo. pp. 263. Boston: S. E. Cassino & Co., 1885.

With the rapidly growing literature pertaining to the bacteria and their relation to disease—a literature which is already assuming colossal proportions—every facility for gaining a comprehensive knowledge of the cardinal facts regarding recent methods and new investigations with the minimum expenditure of time will be appreciated.

Dr. Dolley's book is an instance of with what success a manual may be produced by careful selection and judicious abridgment—the avowed desire to aid and stimulate American investigators furnishing the incentive.

Divided into three parts, the first is a general survey of the subject announced in the title. Anyone proposing to undertake the practical study of the bacteria, could scarcely do better than give the contents of this section a careful reading.

Part II. consists of a very complete epitome of the special methods recommended in the investigation of particular forms, embracing all the microörganisms for which genetic relations to diseases have been claimed.

The unity of the text—not infrequently the interest of the reader as well—has been preserved by relegating to Part III. all formulæ of which mention is made, the bracketed figures affording ready reference. A reciprocal reference to the appropriate text might have been added to each formula, possibly with advantage.

The discussion of each subject is followed by a list embracing all the important references bearing upon the immediate topic.

Careful examination convinces us that the book is one of real worth, which will find its place on the worktable of those already engaged in bacteria investigations, and which will be especially valuable, as a reliable guide, to those about to enter upon such studies.

SOCIETY PROCEEDINGS.

THE PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, February 22, 1886.

The President, S. Weir Mitchell, M.D., in the Chair.

Dr. Harrison Allen read a paper on

THE HEADACHES WHICH ARE ASSOCIATED CLINICALLY WITH CHRONIC NASAL CATARRH.

(See page 288.)

Dr. Carl Seiler said that we all know that there is more or less headache associated with nasal catarrh, but how far exact lesions give rise to these exact pains had not before been described in so many words. He thinks, with Dr. Allen, that the headache of reflex origin is largely due to pressure upon one of the surfaces of the nasal chambers. It is a curious fact, in his experience at least, that in most cases the headache of catarrh occurs on the left side of the head; while, on the other hand, obstruction of the right nostril is much more common than that of the left. He has observed several cases in which the pain was referred to the teeth and to the ear, which, as Dr. Allen has remarked, is very rare. He remembered three cases which came under his notice lately. Two of these patients complained of toothache, or rather of a peculiar pain in the upper jaw, which might be called toothache. After careful inspection by skilful dentists, the teeth were pronounced perfectly sound, and local applications for the relief of the catarrh also relieved the toothache. The third, a lady, complained of intense pain in the left external meatus, quite deeply situated. In this case applications to the meatus had no effect, but the pain was entirely relieved by local treatment directed to the nose. In neither of these three cases was headache present.

Dr. S. Solis-Cohen said that Dr. J. Solis-Cohen had once told him of a book written by a charlatan, who had discovered the connection between nasal catarrh and headache, and had been quite successful in his treatment of such cases. He had not been able to find the reference to this book, but he had come across a reference to a paper in an early number of the *American Journal of Medical Sciences*, vol. v., describing a case of periodical hemicrania relieved by the expulsion of a calculus from the nose. This is referred to only in relation to the history of the subject. As to the thesis itself, his personal experience is not extensive; but he has seen in the practice of Dr. J. Solis-Cohen a large number of cases in which headache was associated with, and frequently dependent upon, diseased conditions of the nasal passages, and in which relief followed the cure of the local affection. He had not before heard the subject presented in the systematized way in which Dr. Allen had treated it, and consequently was not prepared to discuss his classification.

Dr. Harrison Allen said that Dr. Seiler's remark on the connection between earache and chronic nasal catarrh interested him very much. We are not yet in possession of all the facts necessary to explain this connection. He was glad that Dr. Cohen had referred to

the case of nasal calculus. The cases recorded by others were not mentioned in his paper, since he lacked the necessary time thoroughly to look up the literature. He believed that the subject of headache which is found associated with chronic nasal catarrh, has never been separately considered, nor the differential diagnosis between it and other forms of headache presented. It is well known that the majority of headaches are much alike. As stated in the paper, the brow, temporal, vertex, and occiput are so commonly involved in all headaches that patients do not distinguish between the several sources of pain, and physicians themselves may occasionally be so far misled as to fail to determine the exact cause of the ailment. In all obscure cases of distress about the head, the nasal cavities should be carefully examined.

Dr. Charles K. Mills, at the request of Dr. C. P. Henry, of the Insane Department of the Philadelphia Hospital, exhibited

A CASE PRESENTING CATALEPTOID SYMPTOMS, THE PHENOMENA OF AUTOMATISM AT COMMAND, AND OF IMITATION AUTOMATISM.

This patient had been recently admitted to the Hospital, and no previous history had as yet been obtained. He was a middle-aged man, not unintelligent looking, and in fair physical condition. His condition, and his symptoms had remained practically the same during the short time that had elapsed since admission. He remained constantly speechless, almost continually in one position, would not open his eyes, or at least, not widely, would not take food unless forced, and his countenance presented a placid, but not stupid or melancholy appearance. He had, on several occasions, assumed dramatic positions, posing and gesticulating. It had been discovered by Dr. Henry that the patient's limbs would remain where they were placed, and that he would obey orders automatically. The case had been regarded as probably one of katatonia, but in the absence of previous history it was not known whether or not he had passed through the cycle of mania, melancholia, etc., which constitutes this fully developed disease. He had had, since admission, attacks of some severity, probably, from description, hystero-epileptic in character.

Dr. Mills, in exhibiting the patient, first placed his arms and legs, and body and head in various positions, where they remained until he was commanded to place them in other positions. His mouth was opened, one eye was opened and the other was shut, and he so remained until ordered to close his mouth and eyes. In most of these experiments the acts performed were accompanied by remarks by Dr. Mills that the patient would do thus and so as he was directed.

Various experiments to show automatism at command were performed. Dr. Mills, for instance, remarked that the gentleman was a good violin-player, when the patient immediately proceeded to imitate a violin-player. In a similar way he took a leadpencil, which was handed to him, and performed upon it as if it were a flute. He danced when it was asserted that he was an excellent dancer; placed his arms in a sparring position, and struck out and countered on telling him that he was a prize-fighter; went through many of the movements of drilling as a soldier, such as "attention," "facing," "marking time," "marching," etc. He was told that he was a preacher and must preach, and immediately began to gesticulate very energetically as if delivering an earnest exhortation. He posed and performed histrionically when told that he was an actor, etc. He was given a glass of water and told that it was good wine, but refused to drink it, motioning it away from him. He was then told that it was very good tea, when he tasted it, evincing signs of pleasure. During all these performances he could not be induced to speak; his eyes remained closed, or, at least, the eyelids drooped so that they were almost entirely closed. He showed a few phenomena of imitation, as keeping time and marching to the sound of the feet of the operator, etc.

After exhibiting these phenomena Dr. Mills made the following remarks:

This patient is undoubtedly suffering from some form of mental disorder. The case is probably one of those which would be classed under the head of katatonia, although in the absence of a past history I do not think that I am entirely justified in making this diagnosis. In the affection known as katatonia first described by Kahlbaum, and in this country discussed by Hammond, Spitzka, and others, but most ably and fully by Kiernan, alternate periods of mania, melancholia, and, it is said, cataleptoid states are present.

Taking the patient as we find him, I have no doubt several views will be suggested to those present. One of the first thoughts that would suggest itself to anyone is that the man is simulating. This idea, I believe, can be dismissed. He is, so far as we have been able to determine, a genuine case of mental disorder, the phenomena which have been exhibited here this evening constituting an essential portion of the psychical affection. Many here present, however, are trained in the observance of mental and nervous manifestations, and I would like to hear from them as to the nature of the case.

Taking up the phenomena themselves in detail, let us question ourselves as to their nature. Have we here genuine catalepsy? What constitutes catalepsy? What are the pathognomonic symptoms of this ancient but not well-understood affection. I have recently been interested in the subject of catalepsy, and I find some want of clearness in authorities as to its distinctive differential features. Rosenthal and some others would make waxen flexibility the *sine qua non;* in its absence regarding the case as not one of genuine catalepsy. Waxen flexibility and unconsciousness of surroundings, are the two points upon which most stress is laid by the majority of well-known writers. What is to be understood by waxen flexibility? I take it that it is a symptom which shows itself in the following way: A patient's leg, or arm, or fingers, his head, or his trunk, on being placed without command, or without remark, by the operator in any special position, will there remain as long as it is possible under ordinary physical laws for it to continue in that position. Such limb or part can be moulded like wax or lead into every possible shape, and will there remain independently of, or in spite of, commands to the contrary. The true cataleptic patient, according to this conception, is in such a condition as to consciousness that he is not capable for the time being of understanding or of obeying a command. So far as mentality is concerned, he is a genuine "wax

figure." This, in my opinion, is a very rare condition. I have sometimes almost doubted its existence. I have certainly seen very few cases which would answer to the picture which I have tried to draw.

Certainly, waxen flexibility, as I have thus described, is not present, or at least, not always present in this patient. It is true that even when I say nothing, his limbs will sometimes remain in the grotesque positions in which they are placed; but he is not in a strict sense unconscious of what is being done. The very movements of my hand, my appearance, (for these patients do see, although their eyes are partly closed), may in this peculiar frame of mind suggest to him my wishes. I am inclined to think that many of the cases reported as examples of catalepsy are in reality cases which present phenomena analogous to those shown by this man.

These phenomena are those which have for many years been known and described under various names. I well remember, when a boy, attending a series of exhibitions given by two travelling apostles of animal magnetism, in which many experiments similar to those exhibited this evening were performed upon individuals, selected apparently at haphazard from a promiscuous audience, these persons having first undergone a process of magnetizing or mesmerizing. In the experiments of Heidenhain, of Breslau, upon hypnotized individuals, many similar phenomena were investigated, and described and discussed by this physiologist under the names of "automatism at command," and "imitation automatism." The hypnotized subjects for instance, were made to drink ink supposing it to be wine; to eat potatoes for pears; to thrust the hand into burning lights, etc. They also imitated all manner of movements possible for them to see, or to gain knowledge of by means of hearing, or in any other way. They behaved like imitating automatons, who repeated movements linked with unconscious impressions of sight to hearing, or with other sensory impressions. It was noted in the experiments of Heidenhain, that the subjects improved with repetition. I am inclined to believe that the patient before us performs better to-day than he did yesterday, or the day before. His manifestations, although, in my opinion, not simulated, have been improved somewhat by practice. Charcot, Richer, and their *confrères*, have made similar observations on hysterical and hypnotized patients, which they discuss under the name of "suggestion."

Hammond (*Med. and Surg. Reporter*, vol. xlv., Dec. 10, 1881) suggests the term "Suggignoskism" from a Greek word, which means "to agree with another person's mind," as a proper descriptive designation for these phenomena. In referring to persons said to be in one of the states of hypnosis, he says that he does not believe that the terms hypnotism and hypnosis are correct, as, according to his view, the hypnotic state is not a condition of artificial somnambulism; the subject, he believes, is in a condition where the mind is capable of being affected by another person, through words, or other means of suggesting anything. In the clinical lecture during which these opinions were expressed, Hammond is reported to have performed on four hypnotized young men experiments similar to those which have been exhibited this evening upon this insane patient. His subjects, however, were not cases of insanity. A bottle was transformed by suggestion into a young lady; sulphur was transmuted into cologne; one of the subjects was bent into all sorts of shapes by a magnet; another was first turned into Col. Ingersoll and then into an orthodox clergyman, etc. In reading such reports, and in witnessing public exhibitions of the kind here alluded to, one often cannot help believing that collusion and simulation enter. Without doubt, this is sometimes the case, particularly in public exhibitions for a price. What has been shown here this evening with this man mentally afflicted; what has been shown again and again by honest and capable investigators of hypnotism—prove, however, not only the possibility, but the certainty of the genuineness of these phenomena in some cases.

Dr. H. C. Wood did not see that this case is closely allied to catalepsy. He had never seen a case which he considered genuine, thorough catalepsy. He had seen a number of cases occurring in the somnolent state of cerebral syphilis and various other disorders, in which there is a tendency to catalepsy—of course, using the term in its narrow sense. He believed this to be simply a case of automatism at command. He noticed when Dr. Mills raised the hand, that the man moved his hand rather by his own effort than by permitting it to be lifted by the doctor. This shows that the man interprets the muscular movement just as he interprets the command to march. The apparent catalepsy is simply the result of the command. He had seen exactly the same condition in a child two or three years of age under the care of Dr. de Schweinitz. The child could be placed in any position and would stay there almost indefinitely. He could see very little relation between this and true catalepsy. This is a psychical condition, while catalepsy is probably a disease involving lower nerve centres than are affected in this man.

Dr. Hobart A. Hare said, with reference to Dr. de Schweinitz's case, that it exhibited more of the lead-pipe character than does this one. When the attempt was made to move a limb, it moved in a stiff way. One of the peculiar positions in which the child was placed was to seat it on the floor with the head and feet pointing toward the ceiling. It would remain balanced on the coccyx for some time until it fell over exhausted.

The President preferred to accept the German definition of catalepsy as given by Dr. Mills. In his lifetime he had seen two cases. One for but a few moments before the condition passed off. The other was most extraordinary. Many years ago he saw a young lady from the West, and was told not to mention a particular subject in her presence, or very serious results would ensue. He did mention this subject rather with the desire to see what the result would be. She at once said, "You will see that I am about to die." The breath began to fail, and grew less and less. The heart beat less rapidly, and finally, he could not distinguish the radial pulse, but he could at all times detect the cardiac pulsation with the ear. There was, at last, no visible breathing, although a little was shown by the mirror. She passed into a condition of true catalepsy, and to his great alarm remained in this state a number of days, something short of a week. Throughout the whole of this time she could not take food by the mouth. Things put in the mouth remained there until she suddenly choked and threw them out. She apparently swallowed

very little. She had to be nourished by rectal alimentation. She was so remarkably cataleptic that if the pelvis were raised, so that the head and heels remained in contact with the bed, she would retain this position of opisthotonos for some time. He saw her remain supported on the hands and toes, with feet separated some distance, with the face downward for upward of half an hour. She remained as rigid as though made of metal. On one occasion, while she was lying on her back, he raised the arm and disposed of the fingers in various ways. As long as he watched the fingers, they remained in the position in which they had been placed. At the close of half an hour, the hand began to descend by an excessively slow movement, and finally it suddenly gave way and fell. Not long after this she began to come out of the condition and quite rapidly passed into hysterical convulsions, out of which she came apparently well. He was not inclined to repeat the experiment.

Dr. James Hendrie Lloyd related the following case: A male patient, about twenty-five years of age, presented himself at the Nervous Dispensary, University Hospital, with a history of masturbation, and was then suffering with a consequent sexual hypochondria. His manner and facial expression indicated profound melancholia. He told his story with difficulty, and tended constantly to lapse into silence and brooding introspection. While a relative, who accompanied him, was relating some details of the case, the patient was observed to fasten his eyes steadily on the blank wall and remain in a fixed attitude. On seizing his arms and elevating them above his head, they were found in a condition of true "lead-pipe" flexibility, with prolonged persistence in the positions in which they were passively fixed. At the same time the patient was apparently unconscious, or unmindful, of the experiment; and even required a loud call, accompanied with a decided nudge, to bring him to himself. The case throws some light, possibly, upon the psychology of these interesting conditions. This patient was, no doubt, in an exaggerated state of what is usually called "abstraction of mind," which all persons experience in minor degrees. He was absorbed in his melancholy reflections, and oblivious to peripheral impressions. Subsequent observations failed to discover him in this condition.

Dr. Henry said that the idea of simulation in this case, as has been stated, can unquestionably be dismissed. Before any conceivable motive could be ascribed, the actions were more marked than to-night. Since his admission, five or six days ago, he has quite spontaneously assumed various attitudes—dramatic attitudes, attitudes of prayer, etc. In moving the man's limbs there is considerable of the "lead-pipe" element brought out.

Another feature of the case is that the man has had peculiar convulsions resembling epilepsy. He, however, has not lost consciousness. By vigorous shaking and calling, he could be recalled to himself, but his face is absolutely apathetic, and to all appearances he is unconscious; he also refuses to eat, which agrees with the classical descriptions of katatonia; he has to be fed either artificially, or through the fear of artificial feeding, after the nasal tube has been resorted to once or twice, he will take food without it.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, February 23, 1886.

The President, Charles McBurney, M.D., in the Chair.

EXCISION OF THE ELBOW-JOINT.

The President presented a patient upon whom he had performed the operation of excision of the elbow-joint. Miss F., aged twenty-nine years, had a severe attack of articular rheumatism twenty years ago, which left both elbow-joints ankylosed at an angle of about 95 degrees. The ankylosis was bony between the ulna and humerus, but some power of pronation and supination remained, the head of the radius being free.

The right elbow was operated upon February 3, 1885. The straight posterior incision (von Langenbeck) was made through the soft parts. The humerus was sawn through on the level of the upper third of the epicondyle. The whole of the olecranon, coronoid process, and the head of the radius were removed by a transverse saw cut. The incision through the triceps and its aponeurotic extension to the forearm was carefully stitched with catgut. Bone drainage tubes were used, an antiseptic dressing, and a plaster-of-Paris bandage over all, the forearm being placed at a right angle with the upper arm, and midway between pronation and supination. On the 15th day the first dressing was removed, the wound found healed throughout excepting two points of granulation where the tubes were inserted. Passive motion was begun at once, and thereafter practised every day, the arm for some time being always replaced in a plaster supporting case. Electricity was frequently applied to stimulate the long disused muscles. The patient can now completely flex and extend the forearm, and has excellent power of pronation and supination. When the elbow is raised to a point higher than the shoulder, the forearm being completely flexed, the patient can extend the forearm, holding a three pound dumb-bell in the hand, thus showing the actual power of the triceps.

Dr. William T. Bull read a paper on

THE RADICAL CURE OF HYDROCELE BY ANTISEPTIC INCISION.

At the present moment there may be said to be three methods prominently before the profession for the radical cure of hydrocele: the time-honored injection of iodine, the antiseptic incision and suture of the tunica vaginalis to the scrotal skin, with drainage, proposed by Volkmann, and the more recent method of the injection of carbolic acid, suggested by Levis, of Philadelphia. An important modification of Volkmann's method has been adopted by Bergmann, of Berlin. It consists in the extirpation of all the tunica vaginalis save that covering the testicle. I have had some experience with the antiseptic incision, which I wish to present to the Society, though the general results of that method be familiar to all. But I wish to mention these results because but one or two American surgeons have reported their experience in detail, and because I know that members of the Society have had a large experience with other methods. It is, hence, rather as a suggestion for discussion that I offer these few remarks.

I have operated on fourteen patients in all. One

case may be left out of consideration, since the cure of a large reducible hernia was attempted at the same time and the patient died from peritonitis. Of the thirteen cases, all made satisfactory recoveries but one. This was a laboring man, forty-two years of age, somewhat debilitated from exposure, and lack of food, but presenting no signs of organic disease of internal organs, who had had double hydrocele for six months. Both sides were operated on at once. The wound was irrigated moderately with a 1 : 5000 solution of bichloride of mercury, and a dressing of bichloride gauze applied. In forty-eight hours diarrhœa occurred, this was followed by vomiting, abdominal pain, and tympanites, and on the fourth day he died. At the autopsy there were found only the evidences of violent gastro-enteritis, the rectum containing several patches of gangrenous mucous membrane.

Of the twelve successful cases ten were hydroceles of the tunica vaginalis, and two were hydroceles of the cord. The two latter had existed each for three or four years. The duration of the hydrocele was in six cases about one year; in two cases between one and two years; in two others, three years and over. As regards previous treatment, two had been injected with carbolic acid (one of them on two occasions), one with tincture of iodine, and the rest of them had been tapped or received no treatment. At the time of operation but one sac was observed to be decidedly thickened. This contained one or two calcareous patches, which were cut out. One hydrocele of the cord was as large as a horse-chestnut, found to be made up of five or six cysts. This case carbolic acid had failed thrice to cure; the other hydrocele of the cord was in reality a compound cyst of the head of the epididymis. A number of cysts of the size of a split pea were clustered about the epididymis and contained within a larger cyst, which reached upon the cord for an inch and a half.

In ten patients Volkmann's operation was done; in two (cyst of the cord and epididymis) the entire parietal layer of the tunica vaginalis was excised. Bichloride of mercury, in the strength of 1 : 5000, was used in moderation to irrigate the wounds, and extreme care taken to tie all bleeding points. The incisions were long enough to reach from the top of the sac to the bottom of the scrotum. The tunica vaginalis was united by a continuous catgut suture to the skin, and two or three deeper sutures applied to hold the two halves of the sac in contact. A further effort was made in this direction by the application of the dressing in such a way as to *hold* the serous surfaces together. Bone tubes were used in three cases, rubber drains in nine, and here I may say that the latter were shown to be preferable. The bone tubes softened rapidly, but were not absorbed at all, and did not adapt themselves to the sinuosities of the wound. The dressing was uniformly of peat bags (with bichloride) and bichloride gauze, with occasionally a strip of iodoform gauze over the line of suture, and an outer layer of absorbent cotton. There was no instance of excoriation or marked erythema of the skin. The penis protruded through the middle of the dressing, which was applied snugly with crinoline bandages. One or two patients had to be catheterized for twenty-four or forty-eight hours, but this was the only discomfort experienced. The career of the wounds was in all cases aseptic and without fever. A temperature of 100.6° on the evening of the second or third day, without any acceleration of the pulse, was the greatest constitutional disturbance. With little variation the first dressing remained in place until the seventh day. On its removal the tubes were withdrawn, and a lighter dressing of iodoform or boracic ointment and plain absorbent cotton, supported by a suspensory bandage, substituted. This was changed as often as it became soiled. The patients were allowed to move about a day or two later, but were not, with one or two exceptions, discharged from the hospital till the sinuses were healed. As a rule, primary union was found on removing the first dressing. In six cases this was complete except where the drainage tube emerged. In five, besides the "drain sinuses," there was a strip of granulations along a portion of the line of suture, forming a quite superficial ulcer which scabbed over rapidly. In one case primary union was secured, but an accumulation of pus (without fever) made it necessary to break down the adhesion, and the abscess required two months to heal. The sinuses left after removal of the drain healed without special attention. There was no instance of orchitis or epididymitis or inguinal adenitis. Induration and thickening along the cord which had been noted by others, disappeared by the time the sinus closed, or soon after.

As regards the time occupied by the treatment, I find that the shortest period of confinement to bed was seven days, the longest three weeks; the average stay in bed of all twelve cases was ten days. The shortest stay in the hospital was ten days, the longest sixty days; the average twenty-seven days. Two cases were much slower in healing than the rest—one from the occurrence of the abscess just referred to, the other from unexplained causes. I think with proper care the case could be expected to get through in three weeks. I have had the opportunity of examining five of these patients one year after the operation, and they remain cured. Two have been seen six months, two others four months after operation, and are free from recurrence. Of the remaining three I have no information. I may state further that all were operated upon under ether except one. In this cocaine was used, with the effect of rendering the operation absolutely painless.

The result of the treatment of these thirteen cases may be briefly stated as follows: One has died from mercurial poisoning; twelve have recovered, ten after incision with suture, two after excision of the sac. The wounds, except in one case, have healed without pain or constitutional disturbance, and on an average in twenty-seven days, ten of which were spent in bed. Nine out of twelve cases are known to have had no recurrence at a period of from four to twelve months after the operation.

This list of cases adds one to the two deaths previously reported from this operation. A writer in The Medical News, of May 3, 1884, collected from various sources 330 cases, of which two died from septicæmia or pyæmia. Bramann [1] from v. Bergmann's clinic, has reported 20 cases without any deaths. This would make 363 cases, with 3 deaths, a mortality percentage of 0.82. As to recurrence, I have no further information than that

[1] Berl. klin. Wochen., April 6, 1885.

given of the 330 cases above referred to, where in 5, or 1.5 per cent., it was noted.

The duration of treatment is variously given, and I do not think much stress can be laid on it, since no two surgeons estimate it in the same way. But it is stated by Volkmann to be on the average 12 days, by Juillard 10 days, by Kuester and Rochelt 14 days, by Lister 17 days, Albert 21 days, Albers 5 to 6 weeks, Englisch 15 to 45 days. These figures are from Bramann's article.

The possibility of recurrence is generally admitted, though claimed to be rare, and the cause is found in the failure of the two serous surfaces, after suture, to unite fully. Small cavities are left which are the starting-points of reaccumulation.

In order to decrease the probability of recurrence, v. Bergmann has proposed the extirpation of the parietal layer, and carried it out in twenty cases, as mentioned above. The wounds healed without febrile movement on an average in ten to twelve days, and no recurrence has yet been seen.

From the experience of the two cases of hydrocele of the cord, and one hydrocele of the tunica vaginalis in which the parietal layer was cut away, and another case in which I have lately sacrificed this membrane in a cyst which complicated a varicocele, I can confirm the statement of Bramann, that the method is exceedingly easy, is even more rapid than Volkmann's, since all the time spent in suturing the tunica to the skin is saved, and the conditions for uncomplicated wound healing are more favorable, and the extirpation of all the tunic which gives origin to the cysts seems to leave no chance for recurrence; the functions of the testicle and the cremaster muscle are in no way disturbed, and the cicatrix left is barely perceptible.

The technique of the operation needs but slight mention. The incision should reach from the top of the sac to the bottom of the scrotum, and I prefer to place its lower end behind the testicle, in order that the drainage tube may be out of the way. The tunica is best removed by stretching it on the fingers and cutting through and pushing back the loose connective tissue with blunt scissors. It is much easier than the extirpation of a hernial sac, where the pressure of a truss has made the layers adherent. The membrane is removed clear up to the epididymis and testicle. It is important to be very painstaking with the ligatures, and to have the drain long enough to pass beyond the testicle. In other respects one proceeds as in Volkmann's operation, but the suturing of the wound is simpler as the tension is absent.

The iodine injection has no deaths at its door, but a very considerable number of recurrences have been noted. In 523 cases there have been 44 recurrences, a percentage of 8.4, and acute suppuration has supervened in 5 instances, or 0.95 per cent. (MEDICAL NEWS, as above). The time of treatment at the clinic at Kiel is estimated at eight to nine days; in Billroth's clinic about nine days; in the Charité Hospital at Berlin two to seven weeks. I should think ten days an outside estimate for the cases I have treated in this way, most of which have been in private practice; but I agree with Bramann in assuming that this class of patients, as they have had no wounds, are apt to be dismissed from treatment many days before they are really able to resume their occupations, when there is still much swelling and tenderness present, and that, if we should not call them cured till the parts had been restored to normal appearance, the duration of treatment with iodine injection would cover quite as long a period as that by antiseptic incision.

The carbolic acid injection has as yet caused no fatal results. In eighty-two cases reported by Weir and Abbe, there was suppuration in three cases, in one of which the sac sloughed. One recurrence is noted. The recent statement of Dr. Keyes (*Med. Record*, Feb. 20, 1886), that he has employed it in all classes of cases to the number of fifty, without any accidents, and with perfectly satisfactory results, is enough to warrant its general adoption. But I cannot help thinking that the method is too recent yet for us to get full information as to the percentage of relapses. It is a striking fact that of the thirteen cases I have met with, two had been treated unsuccessfully in this way. As it attempts a cure by the same process as that incited by iodine—an adhesive inflammation, I see no reason to believe that it will ever yield much better results. Fifty years ago the iodine method was reported from the native hospital of Calcutta (quoted by Curling) to have been employed in 2393 cases, with less than one per cent. of failures. But one German clinic has reported recurrence in 15.5 per cent. of the cases. The general impression is that carbolic acid is less painful than iodine, and that it is less irritating.

One fact bearing on the ability of any injection treatment has been demonstrated by the practice of antiseptic incision—that is, the presence of pathological conditions with which the injections could not reasonably be expected to cope successfully. In a total of 123 cases collected by the writer in THE MEDICAL NEWS, "cysts were found on the vaginal tunic, the testicles, or the epididymis in 43; the testicle and epididymis were enlarged in 23; the vaginal tunic was thickened in 54; false membranes were present in 26; and free or attached foreign bodies were met with in 3." The two multiple cysts of the cord to which I have referred, one of which had twice resisted the injection of carbolic acid, go with these other figures to demonstrate to my mind that we must expect a certain percentage of failures.

The small percentage of failures after the antiseptic incision shows it to be, in my opinion, incontestably the surest way of curing any form of hydrocele. And if we add to the operation the extirpation of the tunica vaginalis, the method would be absolutely free from any recurrence. But it is certainly not without risk, even with its small percentage of deaths, 0.82 per cent.; it makes a wound of considerable extent, which exposes the patient to all the accidents of wound healing; it necessitates, if one acts with due caution, longer confinement to bed, and demands rigorous attention to, and every facility for, antiseptic treatment. In view of these considerations I shall be disposed in the future to reserve the operation for cases in which the injection method has failed, or to perform it only upon patients who, with knowledge of its chances, prefer to take them. As to the relative merits of the carbolic acid and iodine injections, I have no opinion to express, based on personal experience; but, from the experience of Weir, Keyes, and others, I should feel warranted in adopting the carbolic acid, and of sticking to it until it is proved less satisfactory than it seems to be at present.

But I believe that the possibility of failure or of an early recurrence should never be left out of consideration in recommending the injection of either agent, and that we should be prepared with every antiseptic precaution to perform successfully the only truly radical operation, that of extirpation of the tunica vaginalis.

Dr. H. B. Sands said that he had listened with much pleasure to the paper read by Dr. Bull, because the operation to which particular reference had been made was one which he had rarely found occasion to perform. He had done it in three instances, all of which had a satisfactory termination. But he thought the paper showed that a major operation should never be done when a minor operation would suffice. His own experience went to show that treatment of hydrocele by iodine injection is not only safer than any other operation, but far more successful than would be inferred from reading Dr. Bull's paper. His own experience may have been exceptional in this regard, but he could recall very few failures in a large number of cases treated. He had supposed that failure after using iodine injection was not infrequently due to its faulty employment, using either too weak a fluid or too small a quantity. He had usually employed the ordinary tincture of iodine, injecting from two to four drachms of it, and leaving it in the sac. He had never known symptoms of iodism to follow, and had almost invariably found the practice to be followed by a cure. His own experience has been that the patient recovers within a week or ten days. He could recall six cases in private practice, in which he had operated within the last eight or nine months, and all these patients had gone out of the house in the course of a week, except one who remained indoors much longer than was necessary for his health. He does not think iodine injections are attended with any risk to life, or with much danger of recurrence of the hydrocele. Of course, as Dr. Bull had said, the incision sometimes reveals pathological conditions with which injections could not be expected to cope. But the best answer to the question will be found in the result of a large experience, and his own experience is very strongly in favor of iodine injections. He could see no excuse for subjecting any patient, suffering with ordinary hydrocele, to the antiseptic operation. As the writer had said, it is necessary to observe strict antiseptic precautions, which might be carried out in large cities and in hospital practice, but to recommend such a method for general use would be very dangerous, and he was very strongly opposed to it because it is only when the iodine treatment has failed, and the pathological condition is such as cannot be removed by the iodine treatment, that it is justifiable.

He had had only a limited experience in the use of carbolic acid, but he had twice seen suppuration follow its use, which he had not seen after the use of iodine; and he doubted whether injection of the sac with iodine is attended with the least possible risk. He had never seen constitutional disturbance which had given him any alarm. He believed that iodine, or perhaps carbolic acid, which might be less painful, is better than incision, which should be reserved for cases in which the ordinary treatment has failed.

Dr. C. K. Briddon had performed Volkmann's operation a number of times, and his experience with reference to cure does not coincide with that of the author of the paper; certainly the period required to effect a cure was much longer. He thought one difficulty is in applying an antiseptic dressing to the scrotum, which is so movable.

He has had quite a large experience with the use of iodine injection, and the results coincided with Dr. Sands's, and he added that he had treated a large number of cases where the patients had not been confined to bed at all. The latter cases were in dispensary practice a good many years ago, and he remembered only one patient whom he visited after his hydrocele had been injected at the dispensary, and that was an old man in whom there was a double hydrocele, and he made the injection on both sides at one sitting. There was quite sharp reaction, but no suppuration occurred. In all the other cases the patients visited the dispensary within four or five days, which, he recollected, was the average period of time they were kept from their work. His method was first to empty the sac, and then inject Lugol's solution, two or three drachms, to which was added a piece of iodide of potassium as large as a pea, to prevent the precipitation of the iodine in the scrotum. He did not remember a single recurrence; if recurrence took place, the patients did not return to him.

He had not used carbolic acid because he had been so well satisfied with iodine. The only disaster which he had had was in one case which he had tapped without injecting iodine, and in which sloughing of the scrotum took place.

Dr. Weir said that in 1882 he had the honor to present to this Society a paper on the subject of carbolic acid injections for hydrocele, as suggested by Levis, of Philadelphia, and he then reported that he had performed Volkmann's operation twenty-seven times, and had gladly abandoned it in favor of the newer method of treatment, which has not only superiority over Volkmann's operation, but also over the iodine treatment, in which he had seen occasional relapses and great pain following immediately after the use of iodine, and also sufficient inflammatory action to keep the patient in bed several days and to give rise to a great deal of suffering. Besides, in his army experience he saw one case of death follow injection of a hydrocele with iodine; but this occurred in a patient who was enfeebled by a recent fever and in whom the inflammation involved the cord and subperitoneal tissues.

He had used now carbolic acid injections over sixty times, and with only two cases in which he regretted its use. Occasionally relapses had occurred; not a large proportion, however, as he could recall only four or five instances where it took place, and in which the patients were cured by a repetition of the same treatment. In three of these the injection was repeated too soon, as subsequent experience showed that a longer delay would have probably resulted in a cure. In one instance, of the two just alluded to, there was quite extensive suppuration following the use of carbolic acid, and in another suppuration was threatened. In the one in which suppuration occurred, a lesson was derived which was of importance to place before the Society and ask attention to it. He had been, up to this time, in the habit of injecting various quantities, from half a drachm to a drachm and a half of carbolic acid after emptying the sac. In this case, quite a large hydrocele, the iodine treatment had been unsuccessful, and the other side of

the scrotum had been treated successfully by incision after the old method. He injected a drachm and a half of carbolic acid, which was followed by the usual absence of pain, but with recurrence of swelling after a few days, which did not subside, but went on to suppuration, and on opening the abscess shreds of membrane were discharged, and finally large masses; in other words, gangrene of nearly the entire tunica vaginalis was produced. Since then he has rarely injected more than half a drachm at a time.

Not that he was dissatisfied with the carbolic acid treatment, but led by a desire to test the operation under cocaine, he had lately performed Volkmann's operation five times with the new anæsthetic, with satisfactory results, one of which was done on a man at the college clinic. The operation was painless. An antiseptic dressing was applied secured by a well-padded compress and a double figure-of-eight bandage, and the man was allowed to go home. Two days afterward he appeared at the hospital for inspection of the dressing, which was still complete. It was an ambulant case throughout, and progressed favorably from the outset, which illustrated that it is possible to keep an antiseptic dressing upon the scrotum when thoroughly applied.

The objection to Volkmann's operation, and to the still more thorough one of Bergmann, is a just one, and its severity was fully appreciated by Koenig, who had stated that if he had a hydrocele he should prefer the injection process rather than undergo such a severe operation for a slight ailment.

He still felt that the painlessness of the carbolic injections and the comparatively slight reaction, as well as the fair amount of certainty of cure, entitle it to the first place in the treatment of these affections of the scrotum.

DR. SANDS said that Dr. Weir confessed, in his cases, to eight or ten per cent. of failures or recurrences. He had not seen any such percentage of failures or recurrences after the iodine treatment.

DR. WEIR referred to Osborn's recent monograph in which he gives fifty-four cases with eighteen failures with the iodine treatment, which is a very large percentage.

DR. GEORGE A. PETERS said that his experience had been chiefly in the use of injections of iodine, and he had been very well satisfied with it; so well satisfied that he had not been tempted to perform Volkmann's operation. As to the method of using it, he injected the pure tincture, and the quantity was two drachms. He thought one reason why occasional suppuration occurs is because there is carelessness in its use, and some of the tincture is allowed to get into the cellular tissue. Observing this precaution, he thought suppuration would seldom take place.

As to duration, he thought that a week or ten days would cover the treatment. As to the number of recurrences, certainly in his experience they had been very small. He had not had any experience in the use of carbolic acid, as the iodine treatment had satisfied him very well.

DR. L. A. STIMSON said that his personal experience in Volkmann's operation had been limited to three cases. The last one came to him shortly after he had seen the same operation performed by a colleague, followed by a recurrence before the patient left the hospital. In this case, that of a young man, he operated about Christmas, making an incision not more than one and a half inches in length, and stitched the edges of the parietal tunica to the skin, and then washed out the cavity of the sac with pure carbolic acid. He did this with the expectation of so modifying the apposed surfaces that union would take place promptly and completely, and in this instance the result justified the hope, as the patient got well without discharge from the wound after the first twenty-four hours. The cure was complete. This was the only case in which he had applied carbolic acid in this manner.

As to the carbolic acid treatment, he had seen one case of suppuration after injection of a solution of carbolic acid in glycerine; he had seen some cases of recurrence after the use of the method; in one of them spontaneous cure took place afterward.

In two cases he had tried another method, namely, injections of chloride of zinc. One was in a lad eighteen years of age, in whom, without drawing off the liquid, he injected half a drachm of a five per cent. solution of chloride of zinc, which caused no pain at the time, but during the afternoon and evening and the following day, the pain was considerable; on the fourth day he drew off four ounces of liquid which was turbid and contained many leucocytes, and the case then went on to recovery without further incident. In another case a weaker solution of the fluid failed, but he thought the method worthy of further trial.

DR. LANGE mentioned one rare occurrence which he had met with in operating according to Volkmann's method; that is, the presence of two or three long hairs taking their origin from tunica vaginalis of the testicle. He excised the hairs, but had not made a microscopic examination of the tissue from which they took their origin. Recovery took place without disturbance. He had not had disagreeable symptoms after Volkmann's operation, which he had performed in a number of cases, but he must say that, as a rule, in cases where the tunica vaginalis is thin and the hydrocele not of long standing, he treated them by the injection of iodine. He had seen recurrence exceptionally even after repeated injections.

He thought that probably for a small percentage of cases the radical operation would always remain necessary; for instance, for those where the tunica vaginalis is very much thickened, or for cases of hematocele where thick fibrinous pseudo-membranes exist. He did not regard the operation as dangerous, if the necessary precautions were taken.

DR. T. M. MARKOE said that the expression of opinion had been so nearly unanimous, and accorded so nearly with his own, that he had but little to add to what had already been said. He was convinced that the success of the iodine treatment depends very much upon the manner in which it is carried out. He had not used the simple tincture, for the reason that the iodine is precipitated by the serous fluid, and is liable to be deposited in a single spot, where it is more likely to produce irritation if irritation is produced at all. He had, therefore, for many years used the strong Lugol solution, in which the iodine is rendered more soluble by the addition of double the quantity of iodide of potassium and in which the iodine is not precipitated by the fluid in the tunica vaginalis; this, in his hands

had been very efficacious. Although he had performed Volkmann's operation a certain number of times in hospital practice, he had in private practice still adhered to the iodine treatment. So far as recurrence is concerned, he could not say which method makes the most certain cure, but the iodine injection is so simple that it can be repeated without difficulty or danger.

The President said that he had met with quite a number of cases of hydrocele in which the patients had reported that they had received injections of iodine, and in some instances two or three times. He had, however, been struck with the ease with which cure is effected in even these cases by repeating the process. He had thought that the recurrence was due to one of two errors —either in not emptying the sac completely, or in using too small quantity of iodine. The operation is so simple, and has been so long employed, that he thought one or both of these errors are very frequently made. His own experience led him to believe that if the fluid is evacuated entirely, and the injection made very fully, using half an ounce instead of a drachm—as was frequently used—of iodine, the success is very great.

Dr. Lange asked what the condition of the tunica vaginalis was after the injections of pure iodine in which cure followed; in other words, does adhesion take place?

Dr. Weir said that in his fatal case adhesion had taken place on the tenth day. In large patches of the serous membranes, and where the two surfaces were yet apart, flocculent lymph in small amounts could be seen.

Dr. Briddon thought that cure occurred in both ways. He had noticed in a number of cases where the pain was severe, we were apt to get consolidation of the tunica vaginalis, while in other cases this did not occur, and the contents of the tunica vaginalis remained fluid. But in either instance cure was produced: in the one by adhesion, in the other by some alteration of the scrotal structure which prevented relapse.

Dr. Lange remarked that the process of adhesion after the inflammatory stage is usually pretty slow, and may extend over a number of weeks. He thought it rather probable that no adhesions take place, but that the tunica vaginalis is restored to its normal absorbing condition.

Dr. Weir said that when he was using the carbolic acid injections, he noticed in some of the earlier cases that there was considerable accumulation of fluid which was absorbed slowly, and he thought he would hasten it by aspiration, but on the introduction of the needle he was able to withdraw only about a drachm of rather gelatinous material, which probably would have gone on to adhesions under such circumstances.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 4, 1886.

The President, A. Jacobi, M.D., in the Chair.

Dr. D. B. St. John Roosa read a paper on.

Limitations in the value of glasses for the improvement of vision and the relief of disease.

He first gave a brief sketch of the progress of ophthalmological science, the invention of the ophthalmoscope by Helmholtz in 1851, and of the English and German system of test-letters in 1854, and went on to say that the vast proportion of eye troubles met with to-day are errors of refraction and accommodation. Defects of sight are only one, and sometimes only a temporarily acting factor of the causes of neuroses.

Having remarked that he was not sure that Donders, in giving us convex and cylindrical glasses, had not rendered as good a service to the human race as any one man; he said that he could perhaps make his subject as clear by a recital of practical cases in his experience as in any other way. Among the cases which he described were the following:

Pain in the back part of the eyes in using them for near objects. In this case the use of glasses alone was insufficient, although hypermetropia was present. By glasses, combined with the use of electricity and moral suasion, the patient was cured.

Frequent winking. In this case all glasses caused a blur; but relief was eventually secured by the use of convex glasses and exercise in the open air. The patient was a clerk in a country store, and in consequence of the long hours demanded of him, was confined within doors most of the time.

Severe neuralgic headache. In this case the patient was a young seamstress, and complete relief was obtained by the use of cylindrical glasses.

Severe headache and distorted vision for close work. The patient was a young woman who had become reduced in circumstances and was obliged to work hard for a living by coloring photographs; but there was little chance of successfully treating her case by attending to the eyes alone. She had myotic astigmatism, and suffered also from uterine disease, as well as overwork and worry.

Sick headaches; hypermetropia. The patient was a woman of forty-three years of age. No relief whatever was given by the wearing of glasses, and it was plain that something else besides hypermetropia was the cause of her trouble.

Nausea and headache. In this case the patient, whose trouble was caused by a serious blow upon the head, suffered from asthenopia, and was unable to use the eyes for close work.

Asthenopia. In this case there was insufficiency of the internal recti, and relief was afforded by the use of electricity and appropriate glasses.

Frequent headaches; myotic astigmatism. Relief from glasses.

Dizziness and double vision. The patient was a young boy who had insufficiency of the internal recti, and nearly complete recovery resulted from the use of glasses.

The last two cases to which Dr. Roosa referred were typical instances of neuroses in which it is impossible to expect complete relief from the wearing of glasses alone. They were two brothers, of neurotic diathesis. He remarked, in closing, that not much could be done for the relief of uterine asthenopia.

Dr. David Webster thought that Dr. Roosa, in his paper, had given an excellent picture of everyday work in hospital and private practice among ophthalmologists, and said that he agreed with him entirely in his opinions. The fact is, that nearly everyone has more or less error of refraction, and out of every hundred persons, not more than five or six would be found entirely free from this. The number of individuals who need the aid of

the ophthalmologist on this account, however, is comparatively small. He agreed with the author of the paper that the condition of the general health is a very important factor. In numerous instances, where this is good, there is no appreciable trouble with the sight; but if, for any reason, it becomes impaired, the eyes at once require attention. He believed, also, with Dr. Roosa, that there is a limitation to the value of glasses in these cases.

As to reflex neuroses caused by eye-strain, he had seen many cases of headache, nausea, etc., cured by glasses or the division of a muscle when it was too strong for its fellow. He had also seen many cases in which marked relief, by means of prisms. was obtained, and in some instances by prisms of very low power. He concluded by relating two cases, in one of which the treatment by prisms of very low power, and in the other by prisms of very high power, was successful.

Dr. Charles Stedman Bull said that he quite agreed with Dr. Roosa that of late, in this city and elsewhere, altogether too many diseases, both reflex and organic, had been considered as attributable mainly to eye trouble; and he believed that the paper would have an excellent effect in disabusing the minds of many of this erroneous impression.

Dr. E. Gruening said that in certain cases of dizziness and diplopia he had been able to relieve the difficulty by simply prescribing window-glass. The glass over one eye is ground, and over the other left plain, so that the patient can see with but one eye; and as long as such glasses are worn, there is no return of the trouble. It is a fact that is apt to be overlooked, however, that often a slight paralysis of the muscles of the eye is only a symptom of some grave systemic disease, such as tabes.

Dr. William Oliver Moore related a case, showing the limitation of the use of glasses in epilepsy.

Dr. R. W. Amidon said that neurologists are convinced of the utility of glasses in only a very limited number of reflex neuroses, and that he was glad to hear Dr. Roosa also express the opinion that the field is quite a limited one. He regretted that he had not spoken in regard to the special location of headaches associated with different forms of eye trouble. In his own experience he had found that the pain is usually frontal when depending on errors of refraction, and posterior when resulting from insufficiency of the interni muscles. Another important point, in regard to which patients often make inquiry, is, as to how long it is necessary to wear glasses in such cases. In many instances the improvement in the general health is such as to enable the patient, on account of the improved condition of the eyes consequent upon this, to dispense with glasses a considerable time before it is necessary to wear them for presbyopia. When, therefore, he is asked by those suffering from asthenopia if they would have to wear glasses constantly, he often tells them that if their general health improves, they will be able to leave them off.

The author of the paper, he said, in conclusion, had hardly laid as much stress on deficiency of the muscles, particularly the interni, as seemed to him advisable. In his own practice, he had seen excellent results in this condition from the use of prisms; but such cases are often difficult to treat, as the insufficiency varies from day to day, improving with the general health, and *vice versâ*.

Dr. Henry G. Piffard exhibited

A NEW ELECTRIC LIGHT.

The apparatus, he said, was made by the Galvano-Faradic Company, of Fourth Avenue, New York, and it had been perfected by two or three suggestions of his own. Its advantages are a portable battery at moderate expense, and a light of fair constancy. The battery consists of six cells, and the light can be maintained without any perceptible diminution for an hour. Such an electric lamp, he said, he had long needed in his own work, for making examinations of cutaneous disease at night and on dark days, and he thought it would be extremely useful to surgeons for night-work.

CORRESPONDENCE.

MEDICINE IN PARIS.

Trouvé's electrical explorer—Chloropeptonate of iron—Constipation cured by hypnotism—Albuminuria in growing children—Grave pulmonary diseases cured by terpine—Double pneumonia treated by pilocarpine.

Paris, February 19, 1886.

M. N., a young man, was recently admitted into M. Richet's wards of l'Hôtel Dieu, accidentally wounded in the knee by a revolver, which he had withdrawn from his belt. The house surgeon made an occlusive dressing. The next morning, when the chief went his rounds, he examined the patient and ascertained the presence of a hard, round ball, which could be moved by the finger. The tract limited by the spot where the ball entered and the one it occupied was inflamed; pressure on the projectile caused violent pain. M. Richet considered it best to extract the ball for the reason that it might be necessary to open the articulation, and the track followed by the ball was too much inflamed to be exposed to the air; the subsequent condition of the patient proved the wisdom of M. Richet's decision; fifteen days later a phlegmonous swelling appeared on the outer surface of the knee, the ball was lodged on the inner side. The patient was very feverish. The abscess was incised and a quantity of pus escaped; fever was intense, but local inflammation gradually subsided. The ball was encysted, M. Richet decided on extracting it, but before operating he ascertained its exact position by using Trouvé's electrical explorer (Trouvé's explorateur electrique).

M. Richet frequently used this apparatus in 1870 and 1871, during the war, also quite recently to explain violent pains in the bladder of a patient who entered the wards with a foreign body in the bladder. Passing a bougie failed to reveal any symptoms suggesting the presence of a calculus. The patient was stubbornly silent, and M. Richet believed that he had introduced a foreign body into the urethral canal. A stone-crusher was introduced into the bladder, and was opened by using Trouvé's apparatus; the foreign body was seized by the instrument, which, being in contact with the electrical explorer, vibration was produced, and revealed the presence of a metallic object.

A few days ago, M. Verneuil, of the Pitié Hospital, also used Trouvé's apparatus. This operation was

more complicated. The patient was formerly a soldier; in 1870 he was shot in the thigh; the ball was lodged deep in the tissues. Some time later on, an abscess formed in the interior of the pelvis, and opened exteriorly. When the patient entered the hospital, there was a fistula damaging the adductor longus femoris muscles; fever and pain were both absent, also chronic septicæmia. M. Verneuil explored with a sound, and ascertained the presence of a bullet. He was proceeding to operate, when a quantity of pus escaped from the inferior portion of the fistula, and the ball, which was encysted and immovable, fell into the wound. All operation was suspended for a time. Later on, the ball was sought for by means of the electrical explorer, which, by its bell, revealed the presence of the ball resting on the sacrum.

Dr. Jules Jaillet has made a series of experiments to determine the action of iron on the organism. The chloropeptonate of iron he considers the best form. He has demonstrated by different experimental means of absorption (hypodermatic, rectal, and venous injections, and ingestion), that this salt of iron is assimilated by the red corpuscles. Chloropeptonate of iron is a veritable chemical combination, which is not affected by the gastric juice, nor the alkalies of the blood; it increases combustion, encourages nutrition, and produces consequently a higher temperature, the process of disassimilation is more active, and the excretions are more plentiful. The appetite increases, but the patient grows thinner; nevertheless, the physiological properties of the blood are improved. Clinical experience has endorsed the truth of M. Jaillet's experimental therapeutics.

Dr. Beuvit du Martouret cures constipation in nervous women by hypnotic suggestion. The patient is sent to sleep, and then it is suggested to her that she is not constipated, but will have a motion on awakening.

M. Eichhorst has observed several instances of albuminuria at the onset of puberty, and quite unexplained by any concomitant pathological condition. The urine contained albumen; sometimes its appearance preceded general disturbance, and disappeared with the other symptoms. The urine was always yellow and limpid; only once did M. Eichhorst find hyaline casts and fat-corpuscles. These attacks of albuminuria reappear after an interval of weeks or months. They may last a day or a week. The prognosis is not serious. Country air and tonics are the best remedies. The symptoms are lassitude, fatigue, inaptitude to work, loss of memory, irritability, changeable temper, and excitability; sometimes there are cephalalgia, vomiting, muscular contractions, and epileptiform convulsions; these latter last but a short time.

Dr. Descroizilles, physician at the Children's Hospital, has successfully treated with terpine a case he describes as pulmonary tuberculosis or chronic bronchitis simulating tuberculosis. The patient was a boy, eight years and a half old, small and delicate; he had been previously treated at the hospital for pleurisy on the right side; he coughed, vomited, spat blood, and had night-sweats; had completely lost his appetite, and was too weak to move. Very little could be learned concerning his antecedents. In the right subclavicular region there were dulness on percussion, a cavernous souffle, and subcrepitant râles. The sputa were abundant; were both mucous and purulent, and were mixed with blood. The axillary temperature rose to 38° C. (100.4° F.), the pulse to 120, and the respirations were 40 to the minute. The regions affected were painted with tincture of iodine. A gramme of phosphate of soda was given daily. The child grew worse; hæmoptysis occurred several times; he alternately suffered from diarrhœa and constipation. The dulness on percussion became more and more marked at the apices of both lungs, but especially so on the right side, where moist râles, almost gurgling, were heard, also a cavernous sound; on the left side moist crackling sounds had been replaced by dry, crackling sounds. The symptoms increased; the child grew weaker; he refused food; his cheeks were sunken and flushed; death seemed imminent. Glycerine and creasote were substituted for phosphate of soda, without any good result. Dr. Descroizilles then decided to administer terpine. Two grammes of this substance were dissolved in 40 grammes of alcohol and 20 of distilled water. The child took three or four teaspoonfuls of this mixture daily, which represented 50 or 60 centigrammes of terpine. A marked improvement followed; less sputa were expelled, and they were free from blood; appetite increased, and the general condition improved. He entered the convalescent period. Lime phosphate and gentian wine were given instead of terpine. In the interval between the beginning of September and the middle of November, the pulmonary symptoms disappeared, the auscultation sounds became healthy, and the child was sent into the country apparently reestablished in health.

Dr. Humbert Mollière has successfully treated double pneumonia with pilocarpine. The patient was exhausted by dysentery and albuminuria, when he was attacked with pneumonia of both lungs. The intestinal disturbance was greatly aggravated. A centigramme of pilocarpine was injected, and was followed by most happy results. The respiratory movement fell from 48 to 24 a minute, and dyspnœa was much relieved. Four hours later, another injection was made, and was repeated the next morning. Each injection was followed by profuse sweats and salivation, and dyspnœa was greatly relieved. The patient rapidly recovered. M. Mollière, in administering pilocarpine, was guided by former experience. An elderly man, with uræmia accompanied by dyspnœa and delirium, who seemed dying, was greatly relieved and ultimately cured by a similar treatment. Dr. Mollière describes another case equally remarkable. A young woman, with a comatose form of uræmia and renal lesion consequent on a cardiac affection, was freed from the comatose condition by pilocarpine injections. In consequence of insufficiency of both renal filtration and pulmonary hæmatosis, the blood was not purified. Uræmia was coexistent with asphyxia. The profuse sweats and abundant salivation resulting from the use of pilocarpine, exerted a purifying influence on the blood sufficient to carry on vitality until the lungs regained their normal permeability and hæmatosis was more thoroughly effected.

NEWS ITEMS.

CHICAGO.

(*From our Special Correspondent.*)

The College of Physicians and Surgeons of Chicago.—The annual commencement of the College

of Physicians and Surgeons of Chicago was held February 23d. Diplomas were conferred upon seventy-one out of the eighty-five members of the senior class. One hundred and sixty-five students matriculated during the winter session.

Dr. E. F. Wells, of Minster, Ohio, has been elected Professor of Materia Medica.

The Health of Dr. N. S. Davis.—We are happy to state that Dr. N. S. Davis has recovered, apparently, completely from his recent attack of hemiplegia. He has resumed the editorial management of the *Journal of the American Medical Association*, and will complete his course of didactic and clinical lectures at the Chicago Medical College and Mercy Hospital.

A New Medical School in the Northwest.—On February 3, 1886, the new buildings of the St. Paul Medical School were formally dedicated.

The St. Paul Medical School was organized in 1871 as a preparatory school, and reorganized on the same basis in 1876. It was organized as a regular medical college, with a graded course of four years, in 1878. In 1880, the college was transferred to Minneapolis, but, in 1885, was brought back again to St. Paul.

With a complete faculty of active and energetic medical men, enthusiastic students, well-equipped laboratories, new and commodious buildings—paid for—and a graded course of instruction extending through three years, the St. Paul Medical College will doubtless, as it deserves to, "flourish, bloom, and bear fruit." Minneapolis, with a total population of 128,000, supports two regular medical schools. St. Paul, with a total population of 124,000, has produced up to the present time but one regular school of medicine. A fair proportion of medical students, both in St. Paul and Minneapolis, are derived from the northern provinces, including Manitoba.

Cook County Hospital.—At an adjourned meeting of the County Board, held on Saturday, February 27th, the following medical men were appointed on the medical staff of the County Hospital, to constitute the Medical Board of that institution:

Surgeons.—Christian Fenger, J. B. Murphy, A. J. Baxter, J. M. Hutchinson, W. P. Verity, Leonard St. John, D. A. K. Steele, E. W. Lee, Truman W. Miller.

Physicians.—Norman Bridge, P. J. Rowan, H. C. Kerber, A. C. Cotton, S. A. McWilliams, G. B. Abbott, John A. Robinson, D. W. Nolan, Andrew J. Cory.

Obstetricians and Gynecologists.—John Guerin, Fred. Heurotin, F. C. Schaefer, George H. Randall.

Ophthalmologist and Otologist.—W. F. Smith.

Pathologist.—Elbert Wing.

Queen Victoria, it is stated, will personally officiate at the corner-stone laying of the new building to be erected on the Thames Embankment by the Colleges of Physicians and Surgeons, the appointed date being March 24th.

The British Gynecological Society numbered four hundred before the close of its first year

A Committee has been organized to collect funds for the erection of a monument to the three distinguished French physicians, Bretonneau, Velpeau, and Trousseau.

First Russian Medical Congress was opened in St. Petersburg on January 7, 1886, under the presidency of Prof. Krassowski.

New York State Medical Association.—The third special meeting of the Fifth District Branch of the New York State Medical Association will be held in Yonkers, March 23, 1886.

Ovation to von Langenbeck.—A banquet attended by an enormous concourse of students and professors, was tendered to Professor von Langenbeck, in Bonn, in February.

Recovery of Dr. Rochester.—The complete recovery of Dr. Thomas F. Rochester, of Buffalo, after a prolonged and painful illness, is announced.

Dr. Filehne, teacher of Pharmacology in the University of Erlangen, has accepted an invitation to the professorship of the same subject in the University of Breslau, in the Chair of the late Dr. Haeser.

NOTES AND QUERIES.

DISCOLORATION FOLLOWING THE EXTERNAL USE OF PYROGALLIC ACID.

To the Editor of The Medical News.

Sir: Allow me to call attention to a correction, as to a matter of fact, in the external use of pyrogallic acid in cutaneous affections; in regard to which I stated in an annotation in the American edition of Reynolds's *System*, vol. iii. p. 886, on the authority of Hebra, that it does not, like chrysophanic acid, discolor the skin.

I have received a note from Dr. M. Magelssen, of Red Wing, Minnesota, informing me that a decided discoloration followed a single application to the face, in a case of psoriasis, of a five per cent. ointment of pyrogallic acid.

Very respectfully,
H. Hartshorne.

Germantown, Philadelphia,
March 1, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 2 TO MARCH 8, 1886.

Williams, J. W., *Major and Surgeon.*—Ordered for duty as Post Surgeon, Vancouver Barracks, Washington Territory.—*S. O. 31, Department of Colorado*, February 20, 1886.

Munn, C. E., *Captain and Assistant Surgeon.*—Ordered for duty as Post Surgeon, Fort Cœur d'Aline, Idaho Territory.—*S. O. 31, Department of Colorado*, February 20, 1886.

Wood, M. W., *Captain and Assistant Surgeon.*—Ordered for duty as Post Surgeon, Fort Walla Walla, Washington Territory.—*S. O. 31, Department of Colorado*, February 20, 1886.

Tremaine, Wm. S., *Surgeon and Major.*—Leave of absence extended six months on surgeon's certificate of disability.—*S. O. 50, A. G. O.*, March 2, 1886.

McElderny, Henry, *Major and Surgeon.*—Leave of absence extended one month.—*S. O. 49, A. G. O.*, March 1, 1886.

Arthur, William H., *Assistant Surgeon.*—To be Assistant Surgeon with the rank of Captain, after five years' service, in accordance with the Act of June 23, 1874. February 18, 1886.—*Circular, A. G. O.*, March 1, 1886.

Bushnell, Geo. E., *Assistant Surgeon.*—To be Assistant Surgeon with the rank of Captain, after five years' service, in accordance with the Act of June 23, 1874. February 18, 1886.—*Circular, A. G. O.*, March 1, 1886.

Birmingham, Henry P., *Assistant Surgeon.*—To be Assistant Surgeon with the rank of Captain, after five years' service, in accordance with the Act of June 23, 1874. February 18, 1886.—*Circular, A. G. O.*, March 1, 1886.

Wyeth, Marlborough C., *Assistant Surgeon.*—To be Assistant Surgeon with the rank of Captain, after five years' service, in accordance with the Act of June 23, 1874. February 18, 1886. *Circular, A. G. O.*, March 1, 1886.

THE ETIOLOGY, MORBID ANATOMY, VARIETIES, AND TREATMENT OF CLUB-FOOT.

Two Clinical Lectures delivered at the Philadelphia Hospital.

BY A. SYDNEY ROBERTS, M.D.,

SURGEON TO THE HOSPITAL, AND ORTHOPÆDIC SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE UNIVERSITY HOSPITAL; INSTRUCTOR IN ORTHOPÆDIC SURGERY IN THE UNIVERSITY OF PENNSYLVANIA, ETC.

LECTURE II.

GENTLEMEN: Our last meeting closed with a brief description of the primitive forms of club-foot. We now pass to the consideration of the treatment of talipes in general, such modifications as may be necessary to correct the deformity in any special case which may come before us being deferred until we discuss the compound forms. Properly to cope with these conditions, it is essential that you should thoroughly comprehend the factors, pathological and mechanical, which produce them. Because of the lack of exact knowledge upon the subject by the profession, many cases of deformity remain uncured, and scores of children, who could otherwise be relieved, are left to the care of inconsiderate instrument-makers. It is only by the intelligent application of measures fitted exactly to the case, that success can be achieved; and the knowledge requisite to do this is not possessed by the mechanician in any greater degree than is the knowledge necessary properly to care for a medical case a part of the education of the apothecary. Nor has the training of the general practitioner been such as to make him an adept in this branch of surgery, and when it is considered how few are his opportunities for seeing many such cases, it is not strange that extreme deformities are frequent, and that their existence and progression should be an opprobrium. It is only by the dissemination of knowledge by clinical teaching, and the establishment of institutions dedicated to the care of these special cases, that a better state of things may be hoped for, and the importance of such measures cannot be overestimated.

The object of treatment in club-foot is not only to remove the existing deformity, but to restore to the foot its functions; and to do this many procedures have been resorted to, which have been in turn discarded. We may consider the methods now in use as *mechanical* and *operative*. First among the former is manipulation, applied so as to stretch the contracted tissues, passive motion, massage, shampooing, and electricity being used the while to aid in the restoration of function. The hand, if pressure and traction to the contracted tissues could be continuously applied by it, would, no doubt, constitute the best instrument for the relief of club-foot; the apparatus which is best adapted to take its place is that which should be relied upon in the mechanical treatment of the deformity.

Massage and electricity serve, in paralytic cases, to restore, as far as possible, the functional activity of the paretic muscles, and should always be employed as adjuvants in such cases.

Tenotomy for the division of contracted tendons, called aponeurotomy when performed upon fasciæ and aponeuroses, was resorted to first by Delpech, of Montpellier, France. It was not, however, generally employed until Stromeyer, of Hanover, rendered it popular. Little introduced the operation into England, and Dickson, of South Carolina, first performed it in America. To Deltmold, of New York, and Mütter, of this city, however, is due much of the credit of making the operation popular in this country. Opinions differ as to the indications for tenotomy and the proper time for its performance; whether, for instance, in cases of congenital talipes, it should be done prior to the time at which the child is able to walk, or subsequently. No difference of opinion can exist as to the advisability of early operation in cases in which the nature or extent of the deformity renders correction by mechanical means alone impossible; but as experience is the only guide to discrimination, mechanical appliances should always be granted a fair trial before resorting to operation. Rigidity, or the reflex spasm caused by point pressure mentioned by Sayre, is not in itself a safe criterion, nor does excessive deformity, taken alone, furnish a reliable indication.

Retentive dressings, such as splints of silicate of soda or plaster of Paris, are used, either alone or after tenotomy, serving to retain the foot in the position acquired after manipulation or operation. The rubber muscle advocated by Richard Barwell, of London, and extensively used by Sayre, may be employed to take the place of paralyzed muscles; or Scarpa's shoe, as variously modified, may be applied to fix the foot and exert traction.

As I mentioned to you at our last meeting, the type of club-foot with which you will most frequently meet is talipes equino-varus. The principles of treatment appropriate to the mechanical conditions present can be applied to any of the other forms. This deformity is well illustrated by the case I now show you.

CASE II. *Congenital double Talipes Equino-varus; Mechanical extension; Recovery.*—Richard C., æt. four months, referred to my care from the Obstetrical Department of this Hospital. The deformity, which in this case affects both feet, takes place upon an antero-posterior and a transverse plane, combining elevation of the heel, *equinus*, and inversion of the foot, with elevation of the internal border of the sole, *varus*. The os calcis is drawn upward by the contraction of the gastrocnemius and soleus, and rotated in such a manner that its posterior border is turned outward and its anterior border inward. The bones of the tarsus, following the direction of the os calcis, are inverted, and the inner border of the sole raised by the action of the tibialis anticus. The altered relation of the bones of

the tarsus leads to alteration in form, especially of the articular facets; and some have considered these alterations as causative. This is by far the most frequent of the congenital forms of club-foot, and it has been argued that arrest of development in bones and muscles is the principal etiological factor. As the various theories on the subject were discussed in our former clinic, they need not detain us here.

The lateral deflection of the anterior portion of the foot, as compared to that of the normal imprint, is well shown in the following cuts. The outline tracings are from impressions of the feet of patients suffering from various deformities, obtained after the method advocated by Rohmer (*Les Variations de Forme Normales et Pathologiques de la Plante du Pied*, Thèse, Nancy, 1879), consisting of first covering the plantar surface of the foot with lampblack, which leaves a correct impression of the sole upon white paper, on which the patients are then requested to walk. To obtain a correct basis of measurement, and still further to carry out Rohmer's researches as a guide to treatment, I selected the medio-tarsal joint as a base line of measurement; erecting upon it a perpendicular corresponding to the long axis of the os calcis. As they are comparatively stable structures in all deflections from the normal condition of the foot, the *position* and character of deformity could be readily determined by a comparison of the degrees of variation.

In the thirty-two normal feet measured, I have found the angle of deflection, which is represented by an imaginary line passing through the head of the metatarsal bone of the great toe, to range between 26 and 37 degrees (*average*, 20 males, 34.8 degrees; 12 females, 31½ degrees); typical examples may be seen in Figs. 1 and 2, *males*, and Figs. 3 and 4, *females*.

Fig. 1.

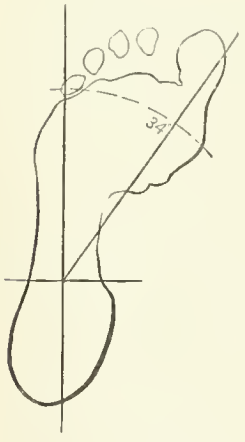

Fig. 2.

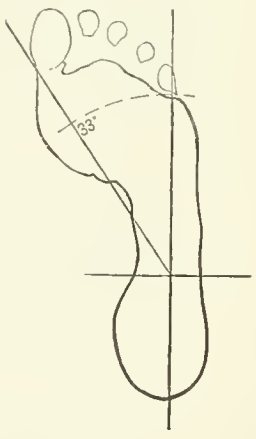

In valgus, on the contrary, the angle of internal deflection is reduced to from 12 degrees in moderate cases to 5 degrees in extreme ones, illustrated by Figs. 5 and 6, which represent the imprint of patient's feet suffering from acquired "flat-foot" of rachitic origin. From an examination of seven cases, I have ascertained the average deviation to be about 8¼ degrees.

The adduction of varus has in two instances reached an internal rotation of 63 degrees. I consider all feet that have an internal deviation in excess of 40 degrees as abnormal. An examination of fourteen cases of varus yields an average of 51 degrees.

Fig. 3.

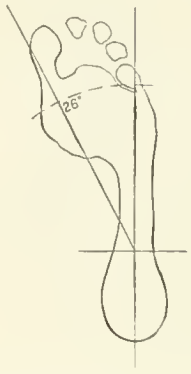

Fig. 4.

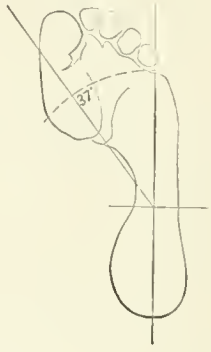
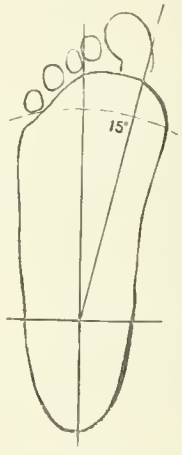


This method of measurement I believe to be of importance as furnishing us with an excellent and accurate

Fig. 5.

Fig. 6.



guide to the amount of deformity, as well as affording an opportunity of determining the improvement that may follow any plan of treatment instituted.

Fig. 7.

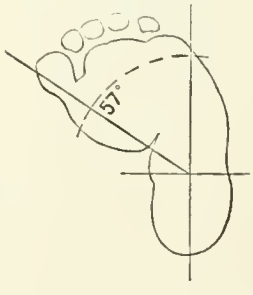


Fig. 8.

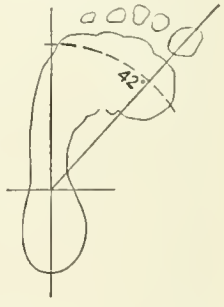
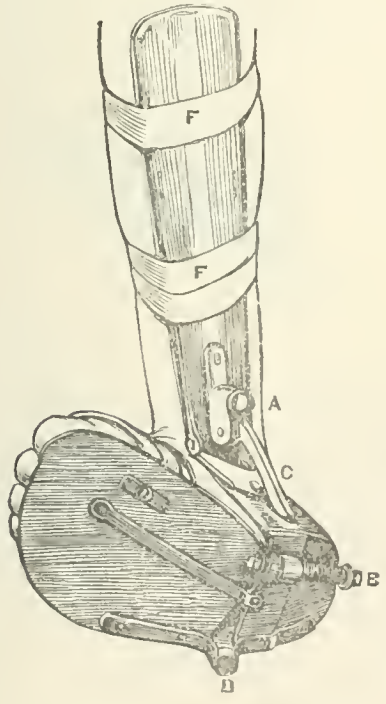


In the correction of equino-varus, as in that of the other compound forms, it is best to divide the process of rectification into two stages, the object being to overcome one of the factors of the deformity before attacking the other. The reason for this will be sufficiently obvious, when it is considered that the altered relations of

the tissues of the foot take place upon two planes at right angles to each other. Our endeavor then should be directed first to the lateral or varus element of the deformity. Manipulation should be systematically used, and while sufficient in very mild cases, is of great service as an adjuvant in severe ones. It should be applied several times daily, and in the following manner: The heel is firmly grasped by one hand, while with the other the anterior portion of the foot is gradually and steadily brought into a position of valgus, and held there for a few moments, then allowed to return to its abnormal position. After the manipulation has been repeated several times at short intervals, the foot may be placed in any light dressing. This splint will retain the foot in its corrected position, and may be modified from time to time to suit the lessened amount of varus. It may consist of material suited to the case. In the milder degrees of the deformity, adhesive plaster wound around the foot and attached to the fibular aspect of the leg answers the purpose, but when greater strength is required splints made of leather, gutta-percha, or hatters' felt may be moulded to the parts, and secured by a roller bandage. These have the advantage over fixed dressings of plaster of Paris in allowing inspection as frequently as may be desired, together with the application of massage, electricity, etc.

But the majority of cases of varus cannot be cured by such simple means. As in this case, which is typical of congenital equino-varus, we have absolute deformity to overcome; tendons and muscles are shortened, and the tissues structurally altered. The so-called

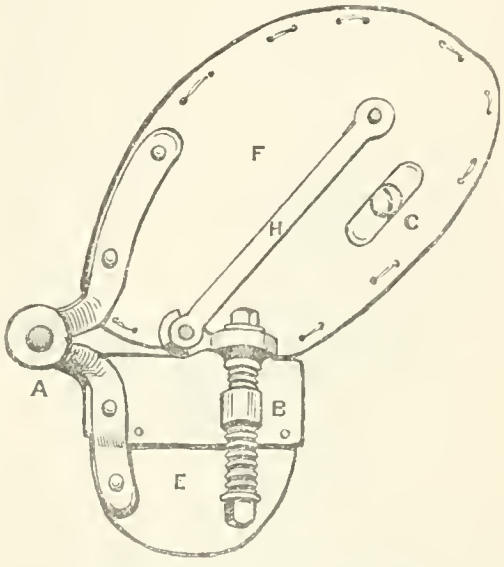
Fig. 9.



"mild measures" will not avail, and time occupied in the trial is wasted. Nothing will be of benefit except the application of instruments, which by their accuracy of construction and power will appropiately stretch the tissues involved, or, after a fair trial of these, operations which will divide the resisting structures.

In such cases the shoe which I now show you (Fig. 9) is of the greatest service. It is a modification of Taylor's ankle support, and in its original form was devised by Shaffer, of New York. To this brace I have given more power by substituting in the sole plate for his extension bar a triple thread screw worked by a key at "B", and by throwing the centre of motion further to the outer side of the sole at "A" (Fig. 10). The in-

Fig. 10.



strument consists of a steel trough fitted to the inner side of the leg extending from the upper part of the tibia to the internal malleolus. A hinge at "C" (Fig. 9), the direction of which is such as to allow pressure exerted upon it at right angles, to operate upon the anterior or lateral deformity, connects this trough with a continuation, or foot portion, which is joined by a plate to receive the foot by an antero-posterior joint, so that the shoe may be accurately adjusted to the "equinus" element of the deformity. The endless screw which I show you at "A" (Fig. 9) is operated by a key, and acts through this hinge upon the anterior portion of the foot. The sole is divided opposite the medio-tarsal joint, and by means of the screw "B" (Figs. 10, 11) acting upon the centre of motion at "A" allows of extreme and powerful abduction of the anterior part of the foot. The apparatus having been applied to fit the deformity, and secured by a bandage ("F F"), the foot is thrown into a position of valgus by means of the screw "A" (Fig. 9) acting upon the hinge "C," and this is supplemented by applying the force of the screw in the sole plate "B" (Fig. 10), which still further acts upon the anterior deformity. It is better to use the apparatus by stretching the tissues several times in succession, and after allowing them to relax, to adjust the brace to the corrected position. Having by these means overcome the lateral deformity, as illustrated in Fig. 12, our attention must be directed to the antero-posterior or equinus element.

To correct this deformity by mechanical means, it is necessary to apply an instrument which, through

the tendo-Achillis, will elongate the contracted posterior muscles of the calf. To accomplish this, many modifications of Scarpa's shoe have been devised. They consist of two steel uprights extending from the

Fig. 11.

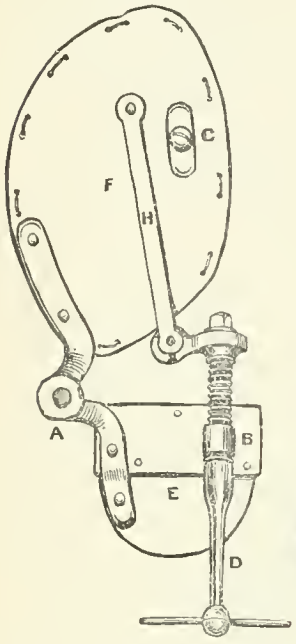


Fig. 12.

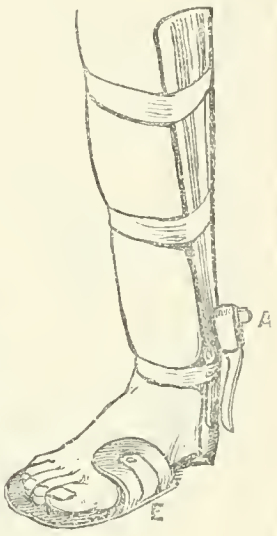
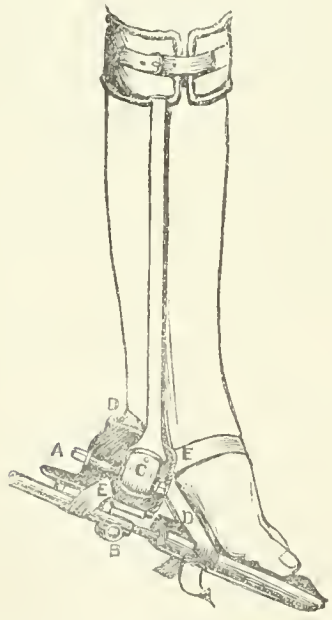


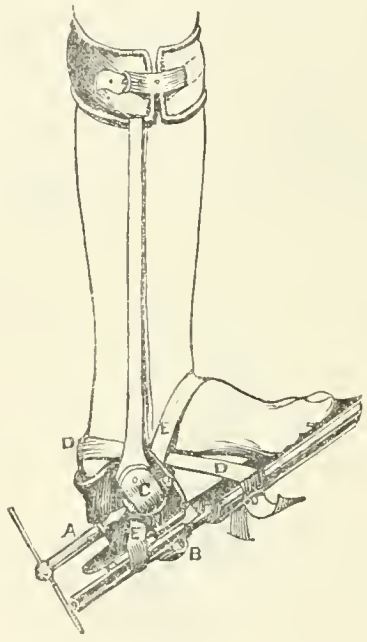
upper part of the tibia to the ankle-joint, and are attached to a heel-cup and sole to hold the foot, the heel being strapped in its place by means of a band of webbing, bandage, or similar material passing over the

Fig. 13.



instep. The sole may, or may not, be divided opposite the medio-tarsal junction. At first sight, such an apparatus would seem to fulfil the indication of applying a force sufficient to flex the foot and stretch the tendo-Achillis, but in practice we find that as the necessary power is exerted, the centre of motion in the instrument being opposite the ankle-joint, the heel-cup slips away from the os calcis, and the posterior border of the foot is found resting upon the top of the heel-cup. To obviate this, Shaffer has in his extension shoe, which I now proceed to apply to this patient (Fig. 13), divided the sole of the brace opposite Chopart's joint, and attached to the anterior portion or sole an extension bar which is worked by a key introduced beneath the heel-cup at "B". The shoe having been applied *extended to* an angle corresponding to the angle of deformity, and the heel secured in its place by a strap passing over the instep "E," the os calcis is further secured by a strap "D" passing around it posteriorly and attached to buckies upon either side of the anterior portion of the sole plate. When flexion is made by the key at "A", which acts upon the endless screw opposite the ankle-joint "C", the tendency of the heel, as you see in Fig. 14, is to slip away

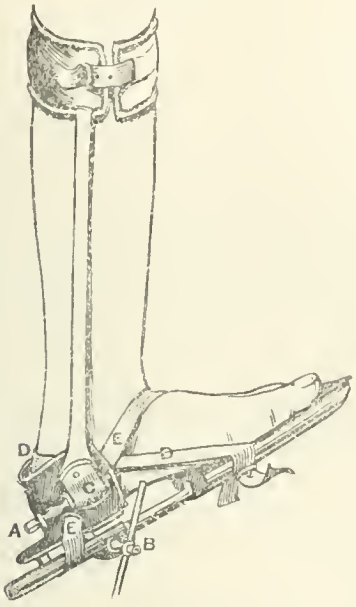
Fig. 14.



and rest upon the upper border of the heel-cup, and the degree of flexion of the foot does not correspond to that of the brace. If now, we insert the key below the heel-cup at "B", and throw the anterior portion of the sole forward, the os calcis is dragged upon by the strap passing over it at "D", and the centre of motion is transferred from a point opposite the ankle-joint, to a point represented by the centre of the strap "E" which passes over the instep, and the heel descends until it rests upon the extension bar. The tendo-Achillis is thus thoroughly put upon the stretch, and may be felt as a tense band (see Fig. 15). The operation is repeated several times at each sitting, and the amount of flexion thus gained is held by readjustment of the brace in the acquired position. No danger need be apprehended from interference with the circulation, if proper precautions be observed; the pressure is not continuous, being rather a *momentary overstretching*, followed by relaxation.

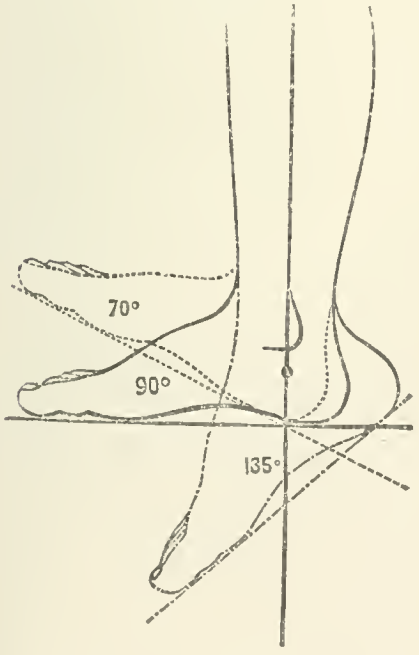
The foot should be inspected daily. After the treatment has resulted in bringing the foot to a right angle with the leg, a retention-shoe with stop-joint should be worn to keep the foot in the corrected position, and a

Fig. 15.



similar apparatus must be applied during the night throughout the treatment. Here let me remark that a cure is not effected when the amount of possible flexion of the foot forms a right angle with the tibia.

Fig. 16.



Referring to the diagram (Fig. 16), you will observe that the normal foot in extreme flexion forms with the leg an angle of about 70 degrees, and at the ankle-joint motion is possible, in the normal condition, through an arc of which the extremes are represented by 135 degrees of extension, and 70 degrees of flexion. Our endeavor in the treatment of talipes equinus should be to make the acquired flexion reach this amount as nearly as possible. In connection with this subject, I wish to call attention to the existence of cases of *incomplete equinus*, designated "non-deforming clubfoot." In this condition flexion is impossible beyond 90 degrees, and the deformity is amenable to the treatment just described.

Case III. *Acquired double Talipes Equino-varus from Tetanoid Paraplegia; Tenotomy of each tendo-Achillis.*—You will recollect the case presented at our last meeting, which comes before us now for operation. In performing tenotomy, much of its success is due to attention to detail. Two tenotomes are necessary; one sharp-pointed with which to puncture the skin, and the other probe-pointed, which is introduced through the puncture, and beneath the tendon or fascia to be divided. The parts having been rendered aseptic by cleansing with a solution of 1 : 2000 of bichloride of mercury, and put upon the stretch by flexing the foot, the puncture in the integument is made over the central portion of the tendon in such a manner that the incision in the skin and that of the deeper tissues shall not correspond after relaxation of the parts. Through this puncture the probe-pointed tenotome is introduced flatwise beneath the tendon, and as close to its deep surface as possible. The cutting edge being now turned toward it, the tendon is divided by a sawing motion of the knife. An assistant keeps the tissues upon the stretch until the operation is almost completed, but relaxes his hold before the tendon is thoroughly divided, to preclude the possibility of the instrument cutting its way through the skin. The tenotome is again turned upon its side, and withdrawn through the puncture, the operator placing his finger over its point of exit, dusting with iodoform, and sealing with a pledget of cotton saturated with compound tincture of benzoin, which forms a pellicle and prevents the entrance of air. After the operation, the foot is placed in the extension brace in order that its degree of flexion may be controlled. This possesses the great advantage over fixed plaster-of-Paris dressings of allowing frequent inspection of the parts.

I shall only mention the operations of myotomy, or division of muscles; tarsotomy, or osteotomy of the tarsal bones; tarsectomy, or the removal of a wedge-shaped piece of bone; open incision, as advocated by Phelps and Hingston, instead of subcutaneous tenotomy; and amputation as a last resort. These are so rarely performed and so little necessary, that it is only essential that you should know that such procedures have been devised.

The next case I have to show you is one of acquired talipes calcaneus.

Case IV. *Acquired single Talipes Calcaneus from Infantile Spinal Paralysis; Application of Barwell's Rubber Muscle; Improvement.*—Maggie B., æt. ten, first presented for treatment in the Orthopædic Dispensary of the University of Pennsylvania. She has kindly consented to appear before you to-day. You will notice the characteristic deformity, the foot being flexed by the action of the anterior groups of muscles, the patient walking upon the heel. In this condition, no treatment does so well as the application of elastic force, advo-

cated by Barwell. The rubber supplies the place of the paralyzed gastrocnemius and soleus, and should be applied as you see in this case. To the shoe are attached two uprights with an antero-posterior joint opposite the ankle-joint. It is important that this joint should be so arranged that while it will permit flexion to any degree, it will stop extension at a right angle. The posterior rubber muscle is attached above to a band which passes around the upper part of the calf and below to the heel of the shoe. Should there be much contraction of the anterior muscles, their tendons may be divided in the manner described, before the application of the apparatus. An operation has been devised for exsection of a portion of the tendo-Achillis for the radical cure of this condition, and consists in the removal of a portion of the tendon, and the stitching together of the divided ends.

The next case I have to exhibit illustrates a very important principle in treatment.

Case V. *Acquired single Talipes Equino-varus; Mechanical extension, Aponeurotomy; Recovery.*—Joseph F., æt. ten years, applied to the Orthopædic Dispensary of the University Hospital for relief from a congenital talipes equino-varus with pronounced *cavus*. The case was treated by mechanical extension, as described when speaking of talipes equino-varus, and resulted in the perfect reduction of the equinus and varus. There remained, however, marked cavus caused by contraction of the plantar fascia. The extension-shoe was applied with the hope of relieving this condition, but without result, when aponeurotomy was resorted to. Several operations were performed, the knife being entered beneath the plantar fascia and the resisting tissues nicked, and the extent of the division was regulated by the degree of relaxation of the plantar arch resulting from each operation. As you see, the boy has made a perfect recovery.

I wish to draw your attention especially to the inefficacy of mechanical means in cases of cavus with marked contraction of the plantar fascia, and the reason will be readily understood if we consider the structure and function of the arch of the foot. In those forms of talipes which depend upon contraction of muscles, mechanical force applied through the tendon will act upon muscular tissue and elongate it. The plantar arch, on the contrary, is constructed with the view of supporting the weight of the body, the tissues entering into its formation are of the most unyielding character, *i. e.*, plantar fascia, and no amount of mechanical power which can be safely applied will suffice in cases in which it is markedly contracted. Aponeurotomy is necessary, and performed tentatively, nicking a little, and repeated as often as necessary, yields the best results.

The last patient to which I shall call your attention to-day illustrates a condition the opposite of cavus, the essential element being relaxation of the plantar tissues.

Case VI. *Acquired double Talipes Planus ("Flat-foot") from Rachitis; Plantar Springs; Improvement.*—John B., æt. thirteen years. This case shows the deformity in a marked degree, the plantar arch being relaxed and flattened, the internal border of the foot resting upon the ground. These cases, in which there is much pain, have received the appellation of "inflammatory valgus." Besides rachitis, the other causes of this deformity are paralysis, ankle-joint disease, and rheumatism. It also occurs in growing children, and in those whose occupation necessitates long standing in one position. In mild cases, the most efficient means at our disposal for its relief, are the plantar springs, which have been applied in this case, with the resulting improvement which you notice. They are made as follows:

A tempered steel spring is placed inside the shank of the shoe, moulded in such a manner as to support the relaxed tissues of the arch, and overcome the tendency of the foot to eversion. In cases of greater severity, it should be supplemented by an ankle support having a pad which will make pressure upon the internal malleolus.

All forms of club-foot may be simulated in the neuromimetic or hysterical conditions. In cases of this kind, the pedal deformity may be accompanied by contractions in other regions, or it may be the only symptom outside the general condition, and the dependence of the local trouble upon the neurotic state may be very difficult to discover. Here, as in neuromimetic affections in other regions, contractions and contractures may so counterfeit their organic prototypes as to render positive differentiation well nigh impossible. In making the diagnosis, the general condition and surroundings of the patient, the hereditary history, together with any fact as to previous mimicry or simulative tendency, should be carefully weighed. The local condition alone is not a reliable guide: the contractions are often as unyielding as in the real deformity; the muscles do not relax during sleep, and the condition may be very persistent. It is only by a careful consideration of each case, and a diagnosis by exclusion, that a correct opinion can be formed.

The care of this condition taxes the patience and ingenuity of the surgeon to the utmost. In few words, the treatment is that of the general neurotic state, coupled with the absolute avoidance of all local manipulations and mechanical contrivances suited to similar local organic deformities, and which would here direct the attention of the patient to the affected member. Despite the most careful general treatment, the deformity may persist for months, as shown by Dr. S. Weir Mitchell,[1] of this city. In this case hysterical single talipes equinus in a young lady of fifteen had continued for two years, notwithstanding the fact that treatment had removed all the more general symptoms of the hysterical state; and it was not until division of the tendo-Achillis, which I performed after consultation with Dr. Mitchell, that the deformity finally disappeared.

ORIGINAL ARTICLES.

PRELIMINARY CONTRIBUTIONS TO THE USE OF A NEW ARTIFICIAL MEMBRANA TYMPANI.[2]

By C. W. TANGEMAN, M.D.,
ASSISTANT TO THE CHAIR OF OPHTHALMOLOGY AND OTOLOGY, MEDICAL COLLEGE OF OHIO.

There has been considerable theorizing as to the function of the membrana tympani ever since its first

[1] Lectures on Diseases of the Nervous System, especially in Women. By S. Weir Mitchell, M.D. P. 129. Philadelphia: Lea Bros. & Co., 1885.

[2] Read before the Cincinnati Academy of Medicine, February 22, 1886.

description by Berengaris, an Italian anatomist, in the fifteenth century (Roosa). In the latter part of the eighteenth century, its middle fibrous layer was described as a muscular layer.

The membrana tympani is found at the bottom of the external auditory meatus, forming the boundary between the middle and external ear. It is about 9 mm. (one-third of an inch) in its greatest diameter, and consists of three layers, viz., the integumentary, or external, the mucous, or internal, and the fibrous, or middle, layers; forming altogether a structure about $\frac{1}{250}$ of an inch in thickness. A small chain of ossicles, three in number, connect the membrana tympani with the middle ear. In its healthy condition it is said to render the tympanic cavity an air-tight space. The vibration of the atmosphere, which is recognized as sound, is carried through the meatus to the membrane, whence it is transmitted by the chain of bones to the fenestra ovalis, or internal ear.

The most frequent cause of destruction of the membrana tympani is the process known as acute inflammation of the middle ear. The reason for briefly alluding to its pathology here will explain itself later on. The tympanum is an irregular space, about one-half of an inch in antero-posterior diameter, one-third to one-half of an inch in vertical, one-twelfth to one-sixth of an inch in transverse diameter. The walls of this space, as well as the ossicles, are lined by a thin delicate muco-periosteal covering, continuous with the mucous membrane of the Eustachian tube. When this membrane is the seat of irritation, it becomes thickened, there is an exudation of mucus and pus—the exudate may be pure pus; the epithelial cells are shed, softening of the tissues due to inflammation takes place, and the membrana tympani, which is the anterior wall of the tympanic space, yields to the increased pressure of the fluids in the cavity.

The membrane may present a variety of appearances. The perforation may show rough edges: there may be more than one perforation; it may be small, or the ulcerative process may sweep nearly all of the membrane away with a portion, or even the entire chain of bones. In cases where the process becomes chronic, there is hyperplasia of the mucous membrane with a formation of nodules and papillary growths. The reparative power of the membrana tympani is very great, but the continued bathing of the middle ear in pus, together with the low form of inflammation, changes the edges of the perforation so as soon to prevent a repair of membrane by granulation.

In considering the physiology of hearing and the requisites necessary for the proper function of all the structures involved, we will see that we must repair the destroyed or altered tissues before we may expect acute hearing. Schwartze states that "any changes within this space which can produce any obstruction to the free vibration of these parts must be the cause of a disturbance of hearing." The theory of the mechanism of hearing, as we find it in many text-books, is that sound proceeding through the meatus striking the membrane causes it to vibrate. The chain of ossicles that are attached to the membrane, and form a system of delicate levers, transmit the vibrations to the labyrinth. Helmholtz has established the theory by experiment that "the power of resonance of curved membranes is greater than those that are tightly stretched," and that this is the condition that we have in the ear. There is claimed to be two curvatures in the membrane, an inward curvature, and a curvature from the handle of the malleus toward the periphery. For perfect hearing, it is necessary that at one time the sound-waves act mostly on the circular, at another time mostly on the radiating fibres of the membrane. Politzer has proven that the chain of bones vibrate, the motions of the malleus, being twice as strong as those of the incus, and four times as strong as those of the stapes.

All of the various theories advanced are open to criticism and it can be demonstrated that they are of but little value. If the vibration of one portion is necessary to hear low sounds, and the vibration of the anterior especially to hear high sounds, how do we reconcile the fact that many patients with large perforations can hear both sounds equally well? On the other hand, if such nicety of motion is necessary between the various ossicles, why does not ankylosis of the joints which follows the different inflammatory actions of the tympanic cavity cause deafness.

That the above theories which have been pretty universally accepted are probably wrong, we shall attempt to prove: it can be demonstrated by a simple clinical experiment. If an individual be taken with perfectly acute hearing and pressure be made on the membrane and the chain of bones so as not to obstruct the sound, but prevent any possible movement of these parts, does it render the ear insensible to sound? On the contrary, hearing is as acute as ever.

It has been pretty conclusively proven that the membrana tympani is not any more essential to hearing than the eyelid is to seeing, yet both are necessary. Its function is wholly to protect the middle ear from the irritating action of the atmosphere. Artificial membranæ tympani were suggested two hundred years ago for the cure of deafness due to perforation and chronic suppuration of the middle ear. But in every instance the application was made with the view to restore the power that the membrane had on the chain of ossicles.

Bauzer was the first to propose this remedy in 1640, by inserting into the meatus a tube of elk's hoof closed at one end by a pig's bladder; but he leaves no record of his cases.

Autenrieth, in the nineteenth century, suggests practically the same thing by using a leaden tube with a fish bladder stretched over one end. Linke reports some good results from this treatment. Yearsley, of London, in 1848, was the first to write about the cure of deafness by the use of an artificial membrane which, in his case, consisted of a bit of sheep's wool curled up and placed in the meatus so as to make slight pressure against the remains of the destroyed membrane. Toynbee some years later constructed an artificial membrane out of a thin circular disk of India-rubber about one-quarter inch in diameter, fastened on the end of a thin silver wire

about the length of the meatus. Toynbee did not lose sight of *his* theory of hearing in the construction of his membrane; it was to act as a receiver of sound; he claimed that the membrane vibrated the same as the natural membrana tympani. These rubber disks often become useless after a few applications; they, in many cases, cause irritation, thereby preventing their use. The wire protruding from the meatus is another objection. In the limited number that tolerate it, there are but few who are benefited by it.

Politzer has modified this invention; he fastens a disk of rubber to the base of a human stapes, by means of thread, and places this in the niche of the fenestra ovalis, claiming for it that sound falling on the affixed stapes is conveyed to the fenestra ovalis, by the inserted stapes. Without comment, we can understand the objection to such a procedure. Hassenstein constructed a small clamp which holds a roll of wadding, this he inserts into the meatus to make pressure on the rim of the membrane remaining, or on the ossicles, and at the same time close the opening.

Hartman constructs an ingenious arrangement out of fishbone which is covered with wadding and placed against the injured membrane.

These and a few other methods have been used for the purpose of improving the hearing in chronic suppuration of the middle ear, but the results obtained have not been in proportion with the efforts that have been made. The main disturbance is undoubtedly in the middle ear and Eustachian tube, and little or no effort has been made to correct this. The suppurative condition is allowed to go on, with the artificial membrana tympani of all of the above observers placed into or over the perforation. Roosa, in his work on diseases of the ear, mentions the membrane as a valuable aid for the cure of chronic suppuration of the middle ear, but he does not explain its action. It certainly acts as an irritant, since patients are advised to wear the rubber disk only a short time each day until they become accustomed to the irritation.

I have treated a number of cases of this kind by means of a substance that will again put the tympanic cavity in its physiological condition—render it an air-tight space. As the source of the pus is the middle ear, and as it oozes out through the perforation in the membrana tympani, would it be good surgery to shut up this secretion by placing a rubber disk over it? Patients improve in hearing in proportion as we are able to restore the involved parts to their normal condition. The meaning of this I can explain no better than by reporting a few cases that I have treated.

Case I.—A. H., aged thirty years, made application for the relief of deafness and a discharge of pus from the middle ear, which had existed for years, with the exception of a few short intervals. The patient had been treated at various times with the result of checking the discharge, but after an acute inflammation of the throat the old trouble began anew. The flow of pus was profuse. An examination revealed a perforation through the membrane, almost circular in shape, about one and one-half lines in diameter, situated in the lower anterior segment. On the left side the perforation was considerably larger, about two inches; the mucous lining of the tympanum was very much thickened; sensitive to the touch and bled readily when handled. The hearing power was considerably reduced, patient could hear a watch tick ten inches from the ear on the right side, eight inches on the left side.

He was very impatient with the ordinary methods of treatment, since the trouble recurred sometimes after the slightest exposure. The middle ear was now daily cleansed by means of the probe and cotton, the Eustachian tube and posterior pharyngeal wall were treated by the application of yellow oxide of mercury ointment applied through the nose, and the tube and middle ear inflated by means of Politzer's air-bag.

This plan of treatment was continued for about a week, when the discharge ceased. The middle ear was also medicated by the ointment on a pledget of cotton, until the parts looked perfectly healthy. I now applied a strong solution of cocaine to the membrane and middle ear, to render them less sensitive. A circular disk of surgeon's rubber adhesive plaster, as nearly the size of the natural membrane as it could be made, was carried to the bottom of the meatus with a delicate angular forceps, so as to close the perforation, and cover the entire membrane. It was pressed in place by means of a cotton-wrapped probe, until it had become firmly adherent, thereby forming again an air-tight space of the tympanic cavity. Inflation no longer yielded the perforation whistle, but the sounds were the same as when a healthy ear is inflated. The hearing was not tested immediately after the application of the plaster.

Patient was asked to return on the following day, for the purpose of inspection. From the observation of others it seemed natural to expect a certain amount of irritation from this foreign body; but it caused no pain, nor a trace of irritation—in fact, the patient did not know, for a few days, whether the disk of plaster was still in the ear or not, except that he could not blow air through his ear, nor could he hear the puff of air when he blew his nose. So the patient continued until he was discharged, when his hearing was perfect, the membranes firmly in position as from the beginning, causing no pain, with hearing absolutely perfect, not only for the watch and conversation, but also for musical sounds of high or low pitch (patient was a musician).

Did this piece of thick sticking-plaster possess acoustic properties, as those described by Helmholtz of the natural membrana tympani, which were absolutely necessary to the proper perception of all kinds of sound? Did the chain of ossicles transmit sound *more* freely now than on the second day after the application of the plaster, when the hearing was found to be but little increased above what it was prior to the introduction of the little disk? Does it not seem that all speculations as to the position and curvature of the membrana tympani are erroneous?

Case II.—The second case differed, in some respects, from the one just reported; we will, therefore, mention only these few points: Wm. S., painter, aged eighteen years, suffered from acute suppuration of middle ear when three years old, as one of the sequelæ of scarlet fever. Since then the discharge

from the ear has continued. The perforations on both sides were quite large, the middle ear was almost filled with a mass of granulations. Air could quite easily be forced through the Eustachian tubes by Valsalva's method. Hearing was reduced to contact on one side, and pressure of the watch against the head on the other side. The treatment was the same as in the first case, but the result was not so good, nor could we expect it. One month after the introduction of the adhesive disks he had improved to hearing the watch at eight inches on one side, and ten inches on the other.

Case III.—Harry S., aged thirteen years, made application for the relief of a chronic otitis media on the right side, which had existed ever since childhood. Hearing was very much diminished, the watch could be heard at a distance of only two inches. The perforation was not large, about one line in diameter, but the low form of inflammation existing for such a length of time had caused quite a damage to the middle ear. After cessation of suppuration the hearing had improved to nine inches This gradually increased, after the perforation had been closed by a disk, to perfect hearing. This last case was examined but yesterday, three months after the operation. The adhesive plaster is in perfect position, and the ear can be inflated without any leakage, although it has been in place three months.

Of the five cases that I can report until now, not one has been inconvenienced by the operation. Cocaine was used to render it painless. No little surprise is manifested at the statement that the disks introduced nearly five months ago are still in proper position, and are just as white and clean as at first. Compare this plan of operation with the use of the artificial membrana tympani above described and introduced as recommended. True, the patient cannot introduce this membrane himself; it is not an easy matter to carry out properly by the physician; but when once introduced it is not in the way like that of Toynbee and others; it need not be removed for cleansing, etc., but becomes, in a measure, a part of the patient himself.

The number of cases treated is small, but the results have been exceptionally good. We need not expect to restore absolutely the hearing of all cases, since irreparable damage may have been done to the ear by the disease. By this procedure I really anticipated more than I have reported; more than a closure by a foreign substance, which is tolerated against the membrana tympani with impunity, and a great improvement of hearing. I expect the closure of the perforation under the adhesive plaster, but I am not able to persuade a single one of my patients to allow me to remove a disk to see in what condition are the margins of the perforation. The improvement of hearing was not immediate, as in the cases reported by Politzer and Troeltsch, but gradual, keeping step, as it seemed, with the restoration that was going on in the middle ear, in consequence of its complete closure.

The failure to cure many cases by the use of Toynbee's membrane, or the wad of cotton, is because of the pathological condition existing in the middle ear. The natural membrane protects only the middle ear, and has nothing to do with vibration. Other things being equal, sufficient sound is carried through the membrane and tympanic cavity by means of the column of air that exists in this space.

REMARKS ON SYPHILITIC DISEASE OF THE LUNGS.[1]

By EDWARD T. BRUEN, M.D.,

Assistant Professor of Physical Diagnosis in the University of Pennsylvania, one of the Physicians to the Philadelphia Hospital, etc.

Before the days of Laennec, indeed from the time of Morgagni in the early part of the eighteenth century, attempts have been made to define the distinguishing features of syphilitic pulmonary processes. In describing syphilitic phthisis, writers have mostly contented themselves with stating that this disease had some influence, more or less distant, on the causes which determine phthisis.

At the present time, while abundant evidence exists relative to the inherited pulmonary syphilis of infants, one cannot affirm that the clinical features of the syphilitic impress on the adult pulmonary substance is as definite as its clinical impress upon many of the other organs and tissues of the body. There has been a paucity of necropsies in the earlier stages of possible pulmonary syphilis, and Greenfield,[2] in his account of five cases of pulmonary or laryngeal lesions out of twenty-two cases of visceral syphilis, says that the pulmonary changes differ but little, if at all, from those which might be produced by other chronic inflammations affecting these particular regions, and he states his belief that the evidence that the pulmonary change in his cases is due to syphilis, rests partly on the analogy with other results of syphilis elsewhere, and partly on the exclusion of other probable causes. Goodhart, from autopsies in Guy's Hospital records during twenty-two years, found 38 cases of chronic lung disease attributable to syphilis, and did not think it possible to distinguish histologically the changes due to syphilis, yet he described certain definite microscopic appearances.

In the Philadelphia Pathological Society,[3] Drs. Pepper and Warder report a case of pulmonary syphilis with autopsy; but in this instance the principal lesion was gummata in the pleura and lung, associated with other pulmonary lesions which were probably secondary. Recenty the number of reported cases of pulmonary syphilis have increased. Paucritius,[4] of Berlin, reports over 110 cases of various forms of syphilitic affections of the pulmonary system, but is impressed with the frequency of an interstitial pneumonia or induration of the connective tissues following the track of the bronchial and pulmonary arteries for a certain distance from the hilus of the organ into its interior.

Reginald Thompson[5] reports over sixty well-marked cases with peculiar physical signs distinguishing the

disease, and which were relieved by antisyphilitic remedies. Frederick Robinson,[1] Gamberini,[2] Schnitzler, Rollet,[3] and Fournier, have also defined certain lesions with special symptoms as due to syphilis. And again Robinson describes two forms of pulmonary syphilis, one in which the greater part of the organ was involved, with the disease appearing primarily at the base extending through the entire lung, posteriorly as well as anteriorly to the apex, and another in which the disease was limited to one or both apices. He adds that the patient in both cases had passed through the stage of secondary syphilis, and the constitution was left free from any outward manifestation of disease, and regarded the first-named condition as "exhibiting little if any difference between it and ordinary pneumonia." He based his differentiation of the syphilitic condition upon the more extensive involvement of the lung in syphilis, and also that the premonitory symptoms local and general were less apparent. Further, in specific pulmonary processes he thought that there was "little if any pyrexia, dyspnœa only in exertion, little or no sputa, and ultimately recovery takes place."

The literature of this subject also includes[4] Mohamed's case of early fibroid syphilitic disease of the lungs, but he also considered the specific character of this growth entirely an open question; and Pye Smith, in reporting a possible case of syphilitic pulmonary disease, writes: "between this syphilis pulmonum and chronic interstitial pneumonia, there is, I admit, no anatomical difference." He bases his distinctive criteria upon the associated changes in the other viscera, and on the reaction to treatment. Green[5] says that the specific fibroid processes differ but little, if at all, from those met with in chronic fibroid phthisis, in chronic pneumonia, and certain forms of pulmonary induration. He urges, however, as distinctive the origin of the growth from the nutritive or bronchial arteries, rather than from the peribronchial or perilobular tissues. He adds, that the changes in the inner coat of the small arteries of the brain in visceral syphilis described by Huebner and Greenfield, have not been shown to occur in pulmonary vessels.

A more recent contribution to this subject is by Porter,[6] of New York, before the New York Post-Graduate Clinical Society, based on 100 cases of pulmonary disease with a positive syphilitic impress, and selected from 1000 cases treated at his clinic. Of the remaining 900, many had pulmonary lesions, and diseases of the various organs, which, in his opinion, were of syphilitic origin, and which, as a rule, responded to a certain line of treatment. In the discussion which followed the presentation of the paper, the experience and opinion of Sturgis and others showed that specific pulmonary processes were less common, considering the great number of adults who had syphilis.

Finally, the writer's observation of pulmonary disease as occurring in the Philadelphia Hospital, covering a period of ten years, has led him to form an opinion that syphilitic processes, excepting in the form of gummata, are infrequent in the lungs. Phthisis in its various forms, however, he has noticed as quite common in syphilitic subjects, arising in the ordinary etiological relation, the deterioration of the general health of syphilitic subjects possibly acting as a predisposing cause; and since the process is oftenest subacute or chronic in these subjects, the symptoms indicate fibroid change as a principal lesion, although in some cases rapid disintegration of the lung ensues. He has, however, notes of a number of cases of gummata in the lung, the pleura, and from the periosteum of the ribs or sternum; but in these cases any distinctive specific features in the associated pathological appearances were wanting to distinguish from the ordinary lesions of catarrhal or tubercular phthisis.

Diagnosis of Pulmonary Syphilis.—I have selected the case of the patient who is now presented, because his history represents a fair example of the clinical features which may be ascribed to pulmonary syphilis.

John C., aged thirty, of healthy parentage, with no inherited tendencies to pulmonary disease, came into the Philadelphia Hospital in February, 1885, with secondary syphilis and characteristic eruption. Within two months of his admission physical examination revealed the signs of consolidation of the apex of the right lung, followed shortly by unequivocal signs of consolidation of the whole upper lobe. In May, general periosteal symptoms developed with inflammation of the ankle-joint. Preceding the development of symptoms of pulmonary consolidation, marked laryngitis with bronchial catarrh existed. The temperature ranged from 100° to 103° for nearly six weeks. At date the physical signs of implication of the upper lobe of the right lung persist, although the process is stationary. There is marked evidence of periosteal thickening and tenderness of the clavicular, tibial, and sternal periosteum. No bacilli have ever been found in the sputa.

In commenting upon the diagnosis of this case, it is evident that it cannot rest upon the physical signs by auscultation or percussion, for these are certainly never characteristic, but the diagnosis in this, as in most cases, must be inferential from the rational history, the periosteal tenderness, and perhaps the absence of bacilli from the sputa.

Pulmonary syphilis is said to develop usually within two to five years from the date of infection, or as late as ten or more years. In the above case the lung implication was much earlier, *pari passu*, with the evolution of the symptoms of secondary syphilis.

The attack of laryngitis during the initial stages is an important symptom, according to most authorities. Yet, as showing the diversity of opinion, Schnitzler lays particular stress on the relation of pulmonary syphilis to specific affections of the larynx, on the simultaneous appearance of the lesions, and the confirmation of syphilis of the lung through coexistent disease of the larynx. On the other hand, in only one of Goodhart's thirty-eight cases, already cited, was the larynx noted to be diseased, and the intestine in only three; while the same author observes that out of 100 post-mortem examinations in ordinary phthisis the larynx has been affected in 24 per cent., and the intestine in 46 per cent.

[5] Op. cit.
[6] New York Medical Journal, August, 1885.

Most authorities lay stress upon the presence of external evidences of syphilis in cases of specific pulmonary disease, yet Mr. Hutchinson has advanced the opinion that visceral and tertiary changes are in inverse ratio to secondary visceral symptoms.

Finally, the distribution of the lesion in the case presented may be considered as tallying with the observations of very many clinicians, but after careful examination of the literature of this subject I would affirm that no satisfactory diagnostic clinical deductions can be made from the location of the lesion, since professional opinion is so widely diverse. Taking Porter's recent paper, in his opinion the apices, on one or both sides, would be the most usual seat of implication, while Goodhart and Green describe the process as affecting the bases of both, or the roots of the lungs, the new growth springing from the bronchial or interlobular bloodvessels, and they state that the vascularity, and the fact that it does not originate in the alveolar or bronchial wall, are the most valuable evidence we possess of the syphilitic nature of the fibroid induration. Again, if the pulmonary lesions are introduced by an attack of pleurisy, the process in the lungs is usually located at one or both bases.[1]

It is claimed by many writers that specific pulmonary lesions disappear under antisyphilitic treatment, but it should be remembered that mercury and iodide of potassium have the property of causing absorption of infiltrations from whatever cause. And, further, whatever may be the results of treatment, if the process be gummatous the clinical results in effecting the resolution and reabsorption of connective tissue hyperplasia are, to say the least, not encouraging.

To give an example of the sort of case which is often considered an example of late pulmonary involvement ten or twelve years after infection, I have selected from my note-book the following history:

A gentleman in 1872 contracted syphilis. He had secondary symptoms, mucous patches in the mouth, alopecia, periosteal pains, etc. These recurred at intervals for a year or two, and then ceased entirely. In the spring of 1883 he began to have lightning pains in the legs, and shortly afterward discovered an absence of patellar tendon reflex. During the summer, ptosis of right eye occurred with enlargement of the pupil, and his general health was much impaired. In May, 1884, although of perfectly healthy stock, with no hereditary predisposition to lung trouble, he contracted an acute laryngitis, which was persistent, and soon followed by general bronchitis. In July, of the same year, slight dulness appeared at right apex with râles at same point, and a few râles, also, at the left apex. The temperature was never high, 100° to 100½°, a few times 101°, with moderate night-sweats. In September, 1884, went to Colorado, and since then all the physical signs have improved, including cough, fever, etc., and the only evidence persisting at date is a slight depression above the clavicle. During the entire course of this history he took iodide in as large doses as the stomach would bear, with occasional use of mercury. At this date he suffers from lightning pains in legs; but there is now a slight response to the patellar tendon, and sometimes a severe nocturnal headache. No bacillus ever discovered in the sputa.

Comments.—This case inferentially might be classed as representing visceral syphilis, and the pulmonary symptoms some part of the general invasion, yet surely the diagnosis could not be regarded as positive.

Dr. John Guitéras, of the Marine-Hospital Service, has sent me a description of certain cases which he had seen at Key West, which he has thought might be considered as indicating specific pulmonary trouble. There were five such cases; all males, three colored, two white. In four of them the left base was implicated, in one the right. The youngest was twenty-five years of age, and the oldest fifty-two years. The history of the first case, which is given in synopsis, is representative of the others.

Case I.—A powerful young mulatto, about twenty-five years of age, complained of suffering for two months with more or less constant, often severe, pain in the left side, and a dry cough, very harassing except when it brought blood. He frequently expectorated blood for three or four days in succession, and then no hæmoptysis would occur for a week or more. The amount of blood expectorated never exceeded (in one day) two ounces, seldom more than one ounce. The blood was sometimes, during the same day, bright red, mixed with mucus; sometimes dark and lumpy. The emaciation had been rapid. The expansion of the lungs was good when the pain was not great. There was an area of slight impairment of resonance on the left side, not extending higher than the seventh rib, but of indefinite outline, and quite difficult to detect. On auscultation there was feeble respiratory murmur, and crepitation higher than would be expected even on the days when hæmoptysis occurred. The crepitation was most distinct, and often limited to inspiration. Sometimes the crepitation was modified by the cough, and seemed to occur in patches, indicating a pleural etiology for the râles. The physical signs suggested localized pleurisy, with small areas of some variety of infiltration of the underlying pulmonary tissue. He was given small doses of iodide of potassium and ergot; but the marked improvement within two weeks suggested an increased dose of the iodide of potassium, and recovery ensued in a little over two months.

The first marked symptoms were, in all cases, pain and hemorrhage, hacking cough, loss of appetite, and feverishness, though the temperature never rose above 101°. In the first day or two after the days on which hemorrhage occurred the evening temperature was 100°–100½°, with normal morning temperature. In the days of interval between the hemorrhage the temperature was normal. Hæmoptysis before treatment was frequent, patients seldom passing a week without hemorrhage, which might last from one to ten days.

Periods of time, varying from one year to four years, had occurred in all five cases between the manifestation of the lung trouble and the last secondary manifestations. All cases were characterized by anæmia, and all recovered completely and rapidly under treatment, as mentioned, so far as the

[1] Ferguson: Some Points in the Relation of Syphilis to Pulmonary Diseases, The Medical News, Jan. 17, 1885.

lung trouble was concerned, but previous to treatment the progress of the cases seemed rapid.

Two of the cases subsequently were submitted to specific treatment, for tertiary bone trouble. In each of the cases the friends of the patients had considered them consumptives.

In conclusion, let me present a brief summary of the symptomatology which has been attributed by the various authorities already mentioned to the clinical picture of syphilitic pulmonary disease.

Symptoms.—The subjective symptoms are numerous, but are often preceded by catarrhal processes in the larynx and bronchial mucous membrane. They are followed by a sense of discomfort, oppression, and uneasiness at the root of the neck, which may increase till actual pain is felt, usually located in the back between the scapulæ, but sometimes radiating through the intercostal nerves around the chest. There may also be difficult respiration, with more or less dyspnœa, especially in the mornings and evenings, besides a sense of heaviness and oppression in the chest, with a feeling of inability to inflate the lungs. These symptoms may be increased on exertion, respiration becoming wheezing, with imperfectly developed asthmatic attacks. Hoarseness, with varying degrees of aphonia, more or less dysphasia, or unequal pupils may be present. In what may be termed the prephysical sign stage, cough may be an initial symptom. It is dry and paroxysmal, with more or less dyspnœa; and, perhaps, like some of the other subjective symptoms, might be attributed to pneumogastric irritation. Rheumatic and nervous symptoms, including sleeplessness and deterioration of the blood-crasis, may testify to the syphilitic infection of the blood.

Objectively, the chest is reported as better developed in the specific form of pulmonary phthisis than in the various analogous forms of pulmonary lesion. The patient may have the appearance of full health. Moxon relates the case of a man employed in carrying sacks of grain, and who was suddenly killed. It was found that he had fibroid induration of a great part of the right and left lungs, besides scars in the liver and testes. When the disease has advanced the ordinary cachectic appearances of phthisis are developed; but the process peculiar to syphilis is, in such cases, long past.

Physical Signs.—The only physical signs, which seem of especial value, are the periosteal thickening of one or both clavicles, substernal tenderness, and œdema, thickening of the tibial periosteum;[1] possibly, also, the absence of bacilli might be included as of importance. The percussion evidences of enlargement of the bronchial glands may be decided. The respiratory murmur may be feeble in volume, and limited to inspiration, especially over the interscapular region.

In one or the other bronchus the respiratory murmur may be more highly pitched than in health, and slightly exaggerated on one side, or at the base of the chest, according to the location of the specific process. The respiratory rhythm is often jerky and paroxysmal. A peculiar alveolar rustle, resembling the sound produced by the rumpling of wall-paper, has been alluded to by Reginald Thompson as characteristic. The absence of râles is commented on by many authorities, and by Porter is explained by the dilated and moist condition of the smaller bronchi; he holds that bronchial râles are produced by the separation of the walls of the finer divisions of the bronchi. Hæmoptysis is infrequent, but is possible through the rupture of newly developed bloodvessels in the new formation in the lung or hemorrhagic infarction of newly developed bloodvessels. The temperature seldom rises much above normal. Inspection and palpation may reveal only a well-developed chest, or the displacements of the viscera common to fibroid forms of phthisis.

All these signs very carefully recited by well-recognized authorities demand attention, but it seems very difficult to assign to them a high degree of value. Certainly these, as well as additional physical signs in specific pulmonary processes unassociated with gummata, must be shared by other forms of fibroid phthisis. When cavities occur, the physical signs cannot be significant.

The specially diagnostic features have already been indicated as including the rational history, the periosteal tenderness, the evidences of the fibroid character of the growth, including dyspnœa, and usually, but not invariably, a low thermometrical record. Perhaps also the absence of bacilli from the sputa, and the dry character of the cough, with recurrent and frequent hæmoptysis.

Summary of Pathological Changes.—1. It may be doubted whether syphilitic pulmonary processes should be entitled syphilitic phthisis because, as Pye Smith observes, that phrase reduces a capital distinction in etiology, prognosis, and treatment; but it would appear that there is a form of pulmonary consolidation which is principally a chronic interstitial hyperplasia, which, by many competent observers, has been etiologically associated with syphilis. "In the case of tubercle the cells are heaped together, and rapidly undergo degeneration apparently from mutual compression and destruction. In syphilis the cells are more distinctly separate, and the mechanism of degeneration appears to be entirely distinct. Mingled with the sound cells, other cells of fusiform or irregular shape soon appear, and these, in their growth, are transformed into a very complete tissue, much resembling granulation tissue or sarcoma. This growth is highly *vascular*, the cells are frequently of large size, the protoplasm abundant, and the nucleus and nucleolus distinct. Indeed, the growth seems to be in a process of very complete organization. But at this point a change seems to occur, sometimes suddenly. The tissue remains apparently the same, but its vitality is evidently lost, the outline of the growth and the vessels can be seen, but they do not stain with carmine or logwood, and they become of a dead-white color."[1] The vesicles are described as being filled with "red blood-disks, leucocytes, desquamated epithelium, and fibrillated fibrin, identical with that found in the second stage of a lobar pneumonia. Others are filled with de-

[1] Porter "has observed that when the sternum is excessively sensitive the tibial crests are less so, and *vice versa*." See also Levin: THE MEDICAL NEWS, Aug. 15, 1885.

[1] Greenfield, op. cit

colorized round cells, or with round, distinctly nucleated epithelium cells, of a diameter varying from one-fifteen-hundredth to one-two-thousandth, others contained granular degenerating material, which would not stain."[1] In other words, a degenerative catarrhal pneumonia. Cheesy masses occurring in the lungs appear as encapsuled masses rather than as diffused centres of softening. Enlargement and pigmentation of the bronchial glands, associated with evidences of bronchitis with peribronchial thickening, and, possibly, narrowing of the bronchial passages, as compared with non-syphilitic forms of similar lesions, in which the bronchial tubes are more widely dilated. Cases have been reported of nodules of syphilitic new formations in the superior and inferior extremities of the trachea and larger bronchi. The nodules may ulcerate, and, in healing, form cicatricial bands of fibrous tissue, which cause contraction of the tracheal tube transversely, or diminish its length.

The indurative hyperplasia, according to Green and Goodhart, commences around the small interlobular bloodvessels, and not in the alveolar and bronchial walls. The fibrosis is attended with puckerings of the pleura, and is less evenly spread over the lobe than in chronic pneumonia, is nodular rather than diffused. It differs from miner's phthisis in wanting the extreme dilatation of the bronchial tubes, and possessing greater solidity from greater cell-growth. Pleural inflammations are also mentioned, especially thickening. It is evident to the writer, from his experience, that much is yet to be learned on this important subject before a definite conclusion can be formulated; and the final adjustment of the relation of the bacillus tuberculosis to the etiology of pulmonary tuberculosis must be awaited.

2. There is no doubt that gummatous formations in large or small nodules are sometimes developed in the lungs or the pleural tissues, or the periosteum of the thoracic bones.

3. The usual forms of pulmonary phthisis apparently developing in consequence of impaired general health, induced by syphilis, is quite frequent.

4. Pulmonary lesions of a syphilitic character in the fœtus, or in syphilitic infants, are unquestionable.

Prognosis. Treatment.—The testimony of many competent observers seems to point to successful treatment when the usual drugs, viz., mercury and iodide of potassium, in large doses, are administered. The prognosis, it would seem, depends upon an early recognition of the trouble. The ravages of the specific process, however, often produce such loss of substance in the lung that the lesions are irreparable; and, therefore, we cannot always accomplish the brilliant results which usually attend an antisyphilitic treatment when the other viscera are invaded.

ON SPONTANEOUS PHLEBACTERIEKTASIA OF THE FOOT.[2]

By A. G. GERSTER, M.D.,
of New York.

During the past year two cases of this rare and interesting morbid condition came under my observation in the German Hospital. Both patients were boys—one fourteen, the other eighteen years old—and in both cases the beginnings of the disturbance belonged to infancy. The older one declined operative treatment, and withdrew from observation. The history of the patient presented is as follows:

Robert Klaile, æt. fourteen, a well-developed boy, was admitted to the German Hospital, July 2, 1885, on account of a number of rebellious ulcers situated on the dorsum of the left foot. The condition was said to have existed since childhood; no injury was remembered. Physical examination of the internal organs revealed their normal state, with the exception of the heart, which was found to be enlarged, and evidenced a marked increase of the energy of its pulsations. The femoral arteries of both sides were found to beat with unusual strength, and, when somewhat compressed, gave rise to a strong whirr, both to be felt and heard by the stethoscope. On inspection, an increased size of the left foot became manifest, the hypertrophy pertaining to the soft parts as well as to the bones. The length of the right foot was 24 centimetres, that of the left foot 25 centimetres. Their circumference was 23 and 24 centimetres. The dorsum, as well as the sole of the left foot was occupied by a doughy, soft, nodular swelling of irregular and not well-defined outlines. The skin of the plantar surface was normal; but on the dorsum, along the course of the saphenous nerve, a series of roundish, irregular, rather hard, dark blue, partly confluent nodes could be seen. They were partly covered with a thick layer of rough epidermic scales, partly by a closely adherent dry scab. Attempts at removing this were followed by rather copious capillary hemorrhage. Their general aspect was that of teleangiektatic nodes. A number of enlarged veins surrounded these nodes, and could be plainly seen through the skin. If pressure was exerted on the swellings, they could be made to disappear, or at least diminish in size, and also a deep-seated pulsation of the whole mass became at once evident. Compression of the femoral artery promptly suppressed the pulsation, and while the compression of the main trunk lasted the swelling did not resume its former size. On the other hand, if the artery was compressed while the tumors were turgid, pulsation ceased, but there was no appreciable decrease of the size of the swelling to be observed. The stethoscope gave evidence of a strong arterial bruit all over the swellings. There was a marked difference in the temperature in favor of the left foot.

It seemed clear that we had to deal with a mixed angioma, containing the elements of both a cirsoid aneurism and of teleangiektasia with phlebektasia. As there was no history of a gross lesion of the bloodvessels, a chronic inflammatory alteration of the entire vascular apparatus of the foot had to be assumed, which by this time had also reacted upon the femoral arteries and the heart, inasmuch as they too were found to be hypertrophied.

An ablation of the diseased part was proposed, but declined; wherefore having explained the not inconsiderable danger of a deligation of the main artery, and having vainly tried elastic compression

[1] Porter, New York Medical Journal, August, 1885.
[2] Read before the New York Surgical Society, March 8, 1886.

for a considerable time, the patient was anæsthetized on July 7th, and the superficial femoral artery was tied in Scarpa's triangle. Pulsation ceased for a time, but became faintly but clearly noticeable about ten minutes after closure of the vessel; whereupon the external iliac artery was exposed and tied. Pulsation did not return after this. The wounds were closed, not drained, and the limb was enveloped in a thick swathing of cotton batting.

The course of the healing of the wounds was undisturbed and feverless, but the circulation in the limb became so depressed that serious apprehensions were entertained in regard to its preservation. The toes, especially the first and second, were cold and livid, their sensibility was destroyed, and in the course of the first week necrosis of the integument of the terminal phalanges became manifest. At the same time the skin on the outer and posterior aspect of the limb, exactly over the course of the peroneal muscles, sloughed; and on being removed, necrosis of the entire belly of the peroneus longus was ascertained. A fortnight after the operation, the muscle was removed. It had the aspect of a pale, waxy, translucent substance. There was hardly any suppuration, and it was deemed advisable not to leave the sequestration of such a large mass of tissue to the rather uncertain and risky efforts of nature. The toes were also removed. The patient was discharged cured in October, and no pulsation or increase of the tumors were noted at the time. The size of the swellings was somewhat smaller than before the delegation, but there was no hardening or marked shrinking such as would follow obliteration: on the contrary, the dough-like consistency had remained unaltered.

Patient was readmitted to the hospital in Jan. 1886. Pulsation had returned and was just as evident as before the operation. The teleangiektatic spots were all supplanted by ill-conditioned ulcers. The metatarso phalangeal joint of the great toe was open and suppurating, and the boy complained of much pain and discomfort due to the ulcers.

Pirogoff's amputation was done Jan. 29, 1886, with the aid of Esmarch's band: the sections of an unusual number of large vessels, twenty-seven, were taken up and tied before; eleven more ligatures were applied after the removal of the constriction. The segment of the calcaneum was nailed to the tibia, and the wound closed by an interrupted catgut suture. Drainage was effected through a counter-opening made alongside of the tendo Achillis. The first dressing was removed twenty-one days after the operation, and the wound was found firmly united, except along a small portion of the suture, where the rather fine catgut had been absorbed too soon. This narrow strip of granulation, together with the track of the nail, was found cicatrized over five days later, when the second dressing was changed.

The patient has a good stump, and walks on it without support.

A very excellent anatomical study of a case of considerable magnitude, by W. Krause, will be found in the second volume of Langenbeck's *Archiv*, published in 1862. Nicoladoni has also reported three cases: two in vol. 18, pp. 252 and 711; the third one in vol. 20, p. 146, of the same periodical. All, with the exception of one reported by Nicoladoni, were affections of the upper extremity, which is said to be the favorite site of the disorder. Both cases seen by me involved the foot; one the left, the other the right. I may add, that the other case presented, especially as regards the local appearance and situation of the malady, an almost identical state of affairs as the case before you, only of less development.

As regards the treatment, the case presented bears out the experience of others, inasmuch as it demonstrates the futility, in the more extensive cases, of less radical measures than ablation.

MEDICAL PROGRESS.

Combination of Iodoform and Nitrate of Silver as a Caustic.—Malthe speaks highly of the following caustic and alterant treatment in torpid chronic ulcers and fistulæ. The surface in question is sprinkled with iodoform, then the lunar caustic is applied thoroughly, and finally the sprinkling with iodoform is repeated. A slight effervescence is produced with evolution of nitrous acid, iodine, iodide of silver, and perhaps also nitric acid and other combinations, all of which bodies act in their nascent state upon the tissues. The ulcers heal with comparative rapidity, and are protected by an antiseptic layer of iodoform and iodide of silver.—*Journal de Médecine*, February 21, 1886.

Efficiency of Commercial Pepsin and Papain.—Dr. William Murrell records the careful examination of the digestive power of thirteen specimens of commercial pepsin, some of English, others of French, German, or American manufacture. They were all active, but in many the proteolytic power was very small. Only four came up to the standard of the new British Pharmacopœia. The name is evidently no guarantee of purity, for a specimen made by a well-known firm was represented by the figure 871, whilst another, sold under an equally well-known name, had to be satisfied with an award of 162, a state of affairs which is hardly satisfactory The same pepsin is often sold under different names, according to the amount of impurity added. I have before me a table showing the exact quantity dissolved by one grain of all the best-known pepsins, but I do not think it would serve any useful purpose to publish it. Better by far that every medical man should make his own observations and form his own opinion. It may be doubted if the Pharmacopœial description of pepsin as "a light yellowish-brown powder" is a happy one, for the most active specimen was a preparation in scales. The pepsin usually supplied to hospitals is, I am sorry to say, of poor quality, In addition to the thirteen solid pepsins, I examined six liquid preparations, wines, essences, etc., and although ten grains were taken instead of one, the results were unsatisfactory, and the only conclusion I could arrive at was that they were not very reliable, although none of them were absolutely inactive. Having used the carica papaya largely in the treatment of various forms of dyspepsia, I determined to try it against the best pepsins, but found that under the conditions already indicated it was decidedly inferior in activity. I examined

in all six specimens of papaw obtained from trustworthy sources, but only two came up to the Pharmacopœia test. The best papain had about half the activity of the best pepsin. I do not say that in alkaline or neutral media the papains are not more active, but simply that, tested against the best pepsins and by the same methods, they do not give equally good results. Even in a neutral solution the best papain was not equal to the best pepsin in an acid solution. A papaw preparation which in a certain time dissolved 420 grains in an acid solution dissolved 476 grains in a one-fourth per cent. carbonate of soda solution and 535 grains in a neutral solution.

No one can doubt that pepsin is a valuable therapeutic agent, and that it is of the greatest possible use in the treatment of many forms of atonic dyspepsia, flatulence, and gastralgia; but to obtain anything like good results it must be given in doses very much larger than those recommended in the British Pharmacopœia. To give only from two to five grains at a time is a palpable absurdity. The reason that such good results are obtained with pepsin in the treatment of infantile diarrhœa is that it is given in proportionately larger doses. To obtain good results in the treatment of dyspepsia two things are essential—first to test your pepsin, and then to give plenty of it.—*Lancet*, Feb. 27, 1886.

Therapeutics of Gonorrhœa.—Awssitidjiski, as a result of the observation of forty cases of gonorrhœa, recommends the following treatment. During from three to four days ninety grains of salicylate of sodium in six fluidounces of infusion of flaxseed are given daily, together with warm sitz-baths. As soon as the cutting sensation on the urethra has disappeared injections of a two per cent. solution of boracic acid are given from four to six times daily for four days. Finally injections of mercuric bichloride, one part in six thousand, are ordered, and continued until the cure is complete.—*Centralbl. f. Chirurgie*, Jan. 30, 1886.

Induced Epistaxis in Headache.—According to Coiffier, in congestive headache nothing secures relief so quickly as induced epistaxis. To produce free nose bleed, proceed as follows: Cut a little piece of mustard paper, dip it in water, roll it up mustard side outward, and introduce it for a few moments into the nostrils. Slight local abrasion will then readily induce the requisite bleeding.—*Canadian Practitioner*, March, 1886.

Precocious Menstruation.—Wallentin records the rare anomaly of a female infant in whom menstruation began in the fifteenth month, and has continued to her seventh year, up to the date of the present paper. The elimination of blood has occurred every four weeks, and endures from three to four days. At the age of four years it weighed over fifty pounds, breasts well developed, mammillæ prominent and pigmented, mons veneris somewhat hairy. At six and one-half years there was apparently mature sexual and physical development. The mental development, however, corresponds to the age of the child.

Wallentin maintains that the bleeding is distinctly menstrual, basing the assertion upon the absence of any pathological cause, and upon a case recorded by Prochownik (*Arch. f. Gynäk.*, Bd. xvii.), in which, at the autopsy of a three year old infant who had menstruated for two years, there was discovered not only marked development of the ovaries, but a fresh corpus luteum.—*Centralbl. f. Gynäk.*, February 20, 1886.

Removal of both Ovaries during Pregnancy.—At the annual meeting of the Obstetrical Society of London, on February 3, 1886, Mr. Knowsley Thornton presented the following unique case. M. W., married, aged twenty-two, in the third month of pregnancy, was known to be large twelve months before marriage. She is now beyond the size of pregnancy, and has a large fluctuant tumor in the abdomen, which is growing fast. Has suffered from several attacks of pain in the abdomen, with rise of temperature, sickness, and faintness. Diagnosis: ovarian tumor complicated by pregnancy. Ovariotomy advised, and performed Feb. 4, 1885. Dermoid tumors of both ovaries removed. Rapid and uninterrupted recovery. Premature delivery at eighth month. Labor uncomplicated. Lochia normal. Fine healthy child, and plenty of milk to nurse it. On examination, uterus found atrophic; patient, while nursing, suffering from flushes, chills, etc., just as others do who have an artificial menopause brought on by operation.—*Lancet*, Feb. 20, 1886.

Mixture for the Anorexia of Pregnancy.—Forwood recommends the use of the following mixture in cases of loss of appetite in pregnant women:

Pulverized calumba root,		
Pulverized sugar root . . .	āā	15 parts.
Senna leaves		4 "
Boiling water		475 "

Infuse. A wineglassful before each meal.—*L'Union Médicale*, Feb. 27, 1886.

Therapeutic Notes.—Dr. Yeo, of King's College Hospital, in his opening lecture in the course of clinical therapeutics, is reported by *The Lancet* as having made the following practical observations:

1. That in order to derive the full beneficial effect from iodide of potassium in cases of aneurism, the drug must be given in twenty or thirty grain doses three times a day.

2. That arsenic, besides acting well in chronic skin affections, is often of service in cases of angina pectoris, asthma, neuralgias (especially the visceral forms), and in some kinds of anæmia.

3. That aconite is much more certain in its action when given to reduce the temperature and other symptoms of local inflammations in children than it is in the case of adults.

4. That the topical application of opium is a much neglected but useful remedy for the relief of local inflammations, especially when these are traumatic.

Powder for use in Pyrosis.—Monin records favorable results from the exhibition of the following powder in cases of heartburn:

Pulverized phosphate of zinc .		10 parts.
Calcined magnesia . . .		3 "
Pulverized vanilla . . .		1 part.—Mix.

A teaspoonful in a wineglassful of water.—*L'Union Médicale*, Feb. 16, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 20, 1886.

THE DEATH OF DR. FLINT.

BY the death of AUSTIN FLINT, SR., the profession of this country has lost a distinguished representative and a most honored member.

When we hear of the death of a man advanced in life, the shock of the announcement is dulled by the feeling that his work was finished and the inevitable had come, but with Dr. Flint it is far otherwise. We have here the keen sense of the removal of a man in the vigor of his intellectual and bodily powers; of the loss of a veteran, it is true, but of a veteran in full armor, still marching as a leader in the very van of progress. This it is which makes his death untimely and his loss a calamity.

In his ties of birth, education, and work Dr. Flint was singularly fortunate. Born in Massachusetts and educated at Harvard, he enjoyed, as a young man, the best advantages the country afforded, and grew up under influences which fostered in his character the firmness, energy, and determination which he inherited from an old Puritan stock. How much of his professional success in life is to be attributed to good qualities derived from his ancestors is an interesting question, as he is one—perhaps the most notable—of a long list of New England physicians in whose families the practice of the healing art has descended, as a sacred office, from father to son through several generations. Among the circumstances which combined to make Dr. Flint a representative American physician, we must take into account the extent and diversity of his field of labor in the first half of his career. East, West, North, and South may justly lay claim to a share in his professional development, and to the influence upon him of life in Buffalo, Chicago, Louisville, and New Orleans may be attributed in part, at least, his intense devotion to what he deemed the best interests of the profession throughout the country.

It is not our purpose on this occasion to estimate the value of Dr. Flint's work, but we may indicate the two directions in which, as it seems to us, he has influenced the medical thought of his day. No one in this country has contributed so much to our knowledge of the physical signs in pulmonary and cardiac disease, and his labors here will have an abiding interest; and as his early and most important contributions were to these subjects, so the last paper from his pen, in the January number of *The American Journal of the Medical Sciences*, deals with questions which he had made the study of a life. To his teaching during half a century we may attribute the prevalence of more rational ideas upon the nature of disease and the action of medicines. Doubtless it was from his great master, Jacob Bigelow, that he learned the lesson which he illustrated in so many ways in his works on fever and on phthisis, that a knowledge of the natural history of a disease formed the starting-point for its rational therapeutics.

But in a still better way the life which has thus prematurely closed has had an influence widespread, beneficial, and enduring. Not for a moment, in his long career, did Dr. Flint lose sight of the dignity and honor of his high calling. It was his life; in it he may be said to have lived and moved and had his being; in it few have walked more worthily; and in the universal esteem of the profession in this country and abroad, he had a reward dearer to him, doubtless, than the measure of worldly success which fell to his lot.

LORETA'S OPERATION.

IN THE MEDICAL NEWS for April 21, 1883, there appeared the first account of the "digital divulsion of the pylorus," as performed by PROFESSOR PIETRO LORETA, of Bologna, Italy, presented in the English language. A record of the first two operations was read in Bologna before the Academy of Science, by the originator of the method, on February 11th of that year, and the same, in printed form, was sent, with photographs of the two cases, to Dr. Robert P. Harris, of Philadelphia, on March 19, 1883, by Dr. Peruzzi, of Lugo, who now resides in Bologna, and has assisted the Professor in a number of his operations. This monograph, with the illustrations, and a photograph of the operator, may be seen in No. 702, F. B., College of Physicians, Philadelphia, Library.

Finding his method quite successful in overcoming non-malignant stenosis of the pylorus, Prof. Loreta turned his attention to the same condition of the

cardiac orifice, and upon July 9, 1883, not quite ten months after his first essay upon the former, opened the latter by his method of "*rapid divulsion of the cardia*," a long-handled instrument having been contrived for the purpose, because of the impossibility from its location of acting upon this orifice directly by the fingers, as had been done by them with the pylorus.

In a letter from Bologna, dated February 22, 1886, Dr. Harris received from Dr. Peruzzi an authoritative statement of the operations of both varieties, which have been performed by Prof. Loreta during the last three years. This record differs somewhat from that of Ancona, in the *Archives Générales de Médecine*, of Paris, Sept. 1885, pp. 318–334; and of Winslow, in the *American Journal of the Medical Sciences* for April, 1885.
